4. Reads hidden demeaning or threatening meanings into benign remarks or events
5. Persistently bears grudges (i.e., is unforgiving of insults, injuries, or slights)
6. Perceives attacks on his or her character or reputation that are not apparent to others and is quick to react angrily or to counterattack

7. Has recurrent suspicions, without justification, regarding fidelity of spouse or sexual partner

B. Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, or another psychotic disorder and is not attributable to the physiological effects of another medical condition

5th ed.; DSM-5; American Psychiatric Association 2013

Personality Disorders, Table 2 DSM-5 Diagnostic criteria for schizoid personality disorder

A. A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Neither desires nor enjoys close relationships, including being part of a family
2. Almost always chooses solitary activities
3. Has little, if any, interest in having sexual experiences with another person
4. Takes pleasure in few, if any, activities
5. Lacks close friends or confidants other than first-degree relatives
6. Appears indifferent to the praise or criticism of others
7. Shows emotional coldness, detachment, or flattened affectivity

B. Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, another psychotic disorder, or autism spectrum disorder and is not attributable to the physiological effects of another medical condition

5th ed.; DSM-5; American Psychiatric Association 2013

Personality Disorders, Table 3 Diagnostic criteria for schizotypal personality disorder

A. A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Ideas of reference (excluding delusions of reference)
2. Odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstitiousness, belief in clairvoyance, telepathy, or “sixth sense”; in children and adolescents, bizarre fantasies, or preoccupations)
3. Unusual perceptual experiences, including bodily illusions
4. Odd thinking and speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped)
5. Suspiciousness or paranoid ideation
6. Inappropriate or constricted affect
7. Behavior or appearance that is odd, eccentric, or peculiar

8. Lack of close friends or confidants other than first-degree relatives

9. Excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self

B. Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, another psychotic disorder, or autism spectrum disorder

5th ed.; DSM-5; American Psychiatric Association 2013

consistently interpreted as malevolent (see Table 1; American Psychiatric Association 2013). Prevalence rates of PPD range from 1.21% to 4.41% of the general population, 10–30% of inpatient populations, and 2–10% of outpatient populations (Lee 2017; Vyas and Khan 2016; Miller et al. 2001). Regarding sex differences, research is mixed as epidemiological research finds higher rates in females, while clinical samples find higher rates in males (Lee 2017). Common comorbid PDs are antisocial, borderline, narcissistic, and avoidant, while other comorbid diagnoses are panic disorder and substance use disorders (Lee 2017; Vyas and Khan 2016).

Risk factors for PPD include childhood trauma (e.g., emotional, physical, and

Personality Disorders, Table 4 DSM-5 Diagnostic criteria for antisocial personality disorder

- A. A pervasive pattern of disregard for and violation of the rights of others, occurring since age 15 years, as indicated by three (or more) of the following:
1. Failure to conform to social norms with respect to lawful behaviors, as indicated by repeatedly performing acts that are grounds for arrest
 2. Deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure
 3. Impulsivity or failure to plan ahead
 4. Irritability and aggressiveness, as indicated by repeated physical fights or assaults
 5. Reckless disregard for safety of self or others
 6. Consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations
 7. Lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another
- B. The individual is at least aged 18 years
- C. There is evidence of conduct disorder with onset before age 15 years
- D. The occurrence of antisocial behavior is not exclusive during the course of schizophrenia or bipolar disorder

5th ed.; DSM-5; American Psychiatric Association 2013

supervision neglect), as well as physical abuse in childhood and adolescence (but not sexual abuse; Lee 2017). Additionally, disadvantaged backgrounds (e.g., African American, Native American, Hispanic), relationship history (i.e., widowed, divorced, separated, never married), low income, and social stress are all risk factors for PPD (Lee 2017). Individuals with PPD rarely seek treatment, perhaps due to their lack of trust in potential researchers, leading to no clinical trials, and thus no specialized treatment strategies (Lee 2017; Vyas and Khan 2016). Little is known about the effectiveness of PPD psychotherapeutic approaches, although cognitive behavioral therapy (CBT) and psychoanalysis are sometimes used (Lee 2017; Vyas and Khan 2016).

Schizoid personality disorder. Schizoid personality disorder (ScPD) is a pattern of detachment from social relationships and consists of a restricted range of emotional expressions (see Table 2; American Psychiatric Association 2013). Prevalence rates of ScPD are higher for males,

Personality Disorders, Table 5 DSM-5 Diagnostic criteria for borderline personality disorder

- A pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
1. Frantic efforts to avoid real or imagined abandonment. (Note: Do not include suicidal or self-mutilating behavior covered in Criterion 5)
 2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation
 3. Identity disturbance: markedly and persistently unstable self-image or sense of self
 4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating). (Note: Do not include suicidal or self-mutilating behavior covered in Criterion 5)
 5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior
 6. Affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days)
 7. Chronic feelings of emptiness
 8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights)
 9. Transient, stress-related paranoid ideation or severe dissociative symptoms

5th ed.; DSM-5; American Psychiatric Association 2013

although they are still low rates (1–2%) for both sexes (Triebwasser et al. 2012). Common comorbid PDs are paranoid, schizotypal, and avoidant, and other comorbid diagnoses are anxiety disorders and depression (Ekleberry 2009; Pokos and Castle 2006; Bockian 2006).

Evidence indicates that childhood and adolescent major depressive disorder is a strong predictor of adult ScPD – an important factor to note, as this is not a prerequisite in any other PD (Triebwasser et al. 2012). Schizophrenia individuals often lose touch with reality, whereas Cluster A PD individuals do not experience this symptom – a key difference between the conditions. Additionally, having a family member with schizophrenia greatly increases the risk of developing ScPD (Triebwasser et al. 2012).

Personality Disorders, Table 6 DSM-5 Diagnostic criteria for histrionic personality disorder

- A pervasive pattern of excessive emotionality and attention seeking, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
1. Is uncomfortable in situations in which he or she is not the center of attention
 2. Interaction with others is often characterized by inappropriate sexually seductive or provocative behavior
 3. Displays rapidly shifting and shallow expression of emotions
 4. Consistently uses physical appearance to draw attention to self
 5. Has a style of speech that is excessively impressionistic and lacking in detail
 6. Shows self-dramatization, theatricality, and exaggerated expression of emotion
 7. Is suggestible (i.e., easily influenced by others or circumstances)
 8. Considers relationships to be more intimate than they actually are

5th ed.; DSM-5; American Psychiatric Association 2013

Unfortunately, very little additional information is known about the genetic and environmental causes of ScPD. Regarding treatment, those with ScPD are often unresponsive and unwilling to engage in therapeutic relationships; however, research indicates that these individuals end up attending treatment more often when not pressured to engage (Ekleberry 2009). Furthermore, although lacking empirical evidence, the concept of “closer compromise” is a potential first step in treatment, where the individual is encouraged to experience an intermediate position between the states of unbearable anxiety regarding emotional closeness and permanent exile, such that they take risks to create less interpersonal distance, and instead, greater connection, communication, and sharing of ideas with others (Klein 2013). Next, longer-term therapy entails the concept of “working through,” where the goals are to change the old ways of feeling and thinking, and to free oneself from these negative vulnerabilities (Klein 2013).

Schizotypal personality disorder. Schizotypal personality disorder (SPD) is a pattern of acute discomfort in close relationships,

Personality Disorders, Table 7 DSM-5 Diagnostic criteria for narcissistic personality disorder

- A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
1. Has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements)
 2. Is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love
 3. Believes that he or she is “special” and unique and can only be understood by, or should associate with, other special or high-status people (or institutions)
 4. Requires excessive admiration
 5. Has a sense of entitlement (i.e., unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations)
 6. Is interpersonally exploitative (i.e., takes advantage of others to achieve his or her own ends)
 7. Lacks empathy: is unwilling to recognize or identify with the feelings and needs of others
 8. Is often envious of others or believes that others are envious of him or her
 9. Shows arrogant, haughty behaviors or attitudes

5th ed.; DSM-5; American Psychiatric Association 2013

Personality Disorders, Table 8 DSM-5 Diagnostic criteria for avoidant personality disorder

- A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
1. Avoids occupational activities that involve significant interpersonal contact because of fears of criticism, disapproval, or rejection
 2. Is unwilling to get involved with people unless certain of being liked
 3. Shows restraint within intimate relationships because of the fear of being shamed or ridiculed
 4. Is preoccupied with being criticized or rejected in social situations
 5. Is inhibited in new interpersonal situations because of feelings of inadequacy
 6. Views self as socially inept, personally unappealing, or inferior to others
 7. Is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing

5th ed.; DSM-5; American Psychiatric Association 2013

Personality Disorders, Table 9 DSM-5 Diagnostic criteria for dependent personality disorder

A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
1. Has difficulty making everyday decisions without an excessive amount of advice and reassurance from others
2. Needs others to assume responsibility for most major areas of his or her life
3. Has difficulty expressing disagreement with others because of fear of loss of support or approval (Note: Do not include realistic fears of retribution)
4. Has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgment or abilities rather than a lack of motivation or energy)
5. Goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant
6. Feels uncomfortable or helpless when alone because of exaggerated fears of being unable to care for himself or herself
7. Urgently seeks another relationship as a source of care and support when a close relationship ends
8. Is unrealistically preoccupied with fears of being left to take care of himself or herself
5th ed.; DSM-5; American Psychiatric Association 2013

cognitive or perceptual distortions, and eccentric behavior (see Table 3; American Psychiatric Association 2013). Prevalence rates of SPD range from 1% to 5% of the general population, and are three times higher than schizophrenia (Kwapil and Barrantes-Vidal 2012). Rates on sex differences are mixed, although there is support for higher rates in males (Ryan et al. 2013). Moreover, females exhibit more *positive* symptoms (e.g., delusions), whereas males exhibit more *negative* symptoms (e.g., flattened affect; Kwapil and Barrantes-Vidal 2012). In clinical terms, positive symptoms are changes in thoughts/feelings that are added to one’s experience (e.g., delusions), whereas negative symptoms are thoughts/feelings that are removed from one’s experience (e.g., flattened affect). Comorbid PDs include paranoid and schizoid (paranoid encompasses suspiciousness, while schizoid

Personality Disorders, Table 10 DSM-5 Diagnostic criteria for obsessive-compulsive personality disorder

A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
1. Is preoccupied with details, rules, lists, order, organization, or schedules to the extent that the major point of the activity is lost
2. Shows perfectionism that interferes with task completion (e.g., is unable to complete a project because his or her own overly strict standards are not met)
3. Is excessively devoted to work and productivity to the exclusion of leisure activities and friendships (not accounted for by obvious economic necessity)
4. Is overconscientious, scrupulous, and inflexible about matters of morality, ethics, or values (not accounted for by cultural or religious identification)
5. Is unable to discard worn-out or worthless objects even when they have no sentimental value
6. Is reluctant to delegate tasks or to work with others unless they submit to exactly his or her way of doing things
7. Adopts a miserly spending style toward both self and others; money is viewed as something to be hoarded for future catastrophes
8. Shows rigidity and stubbornness
5th ed.; DSM-5; American Psychiatric Association 2013

encompasses social disinterest characteristics), while other comorbidities are mood disorders, anxiety disorders, and substance use disorders (Kwapil and Barrantes-Vidal 2012; Ryan et al. 2013). It is important to note that although SPD shares some similarities with other Cluster A PDs, this is the only one that involves magical beliefs or unusual perceptual experiences.

Similar to ScPD, risk factors for SPD include a relative with schizophrenia, indicating the importance of heritability, yet additional information on genetic factors is sparse (Kwapil and Barrantes-Vidal 2012). Furthermore, several environmental factors are associated with SPD, such as maternal smoking during pregnancy, maltreatment, early cannabis use, and childhood abuse, which all increase one’s vulnerability to schizotypy traits (Kwapil and Barrantes-Vidal 2012; Ryan et al. 2013). Currently, there are no randomized controlled trials for SPD, consistent

with the rest of the Cluster A PDs; however, the most promising treatment is derived from treating other schizophrenia spectrum disorders (Ryan et al. 2013). Examples of this include: CBT focused on alleviating positive and negative symptoms, Cognitive Training designed to address cognitive deficits, social skills training aimed to increase interpersonal functioning, family interventions, and last, interventions targeted at cannabis use (Ryan et al. 2013).

Cluster B

Antisocial personality disorder. Antisocial personality disorder (ASPD) is a pattern of disregard for, and violation of, the rights of others (see Table 4; American Psychiatric Association 2013). Additionally, the individual must be at least 18 years old, and must have presented with “conduct disorder with onset” before the age of 15 (American Psychiatric Association 2013). According to the DSM-5, children with conduct disorder must meet diagnostic criteria within the following categories: aggression to people and animals, destruction of property, deceitfulness or theft, and/or serious violations of rules (American Psychiatric Association 2013). Lifetime prevalence rates of ASPD are 4.5–6% in males and 0.8–1.9% in females, as ASPD is more common among males than females (De Brito and Hodgins 2009). Prevalence rates in the general population are low with 1% of males and 0.2% of females, but approximately 50% of prison inmates are diagnosed (De Brito and Hodgins 2009; Sutker and Allain 2002). Comorbid PDs include borderline and histrionic, and other comorbidities include substance use disorders, anxiety disorders, and depressive disorders (Meloy and Yakeley 2014; De Brito and Hodgins 2009; Sutker and Allain 2002).

Common risk factors stem from the prevalence of conduct disorder, as this is a prerequisite to ASPD. Risk factors for conduct disorder include family factors (e.g., psychiatric problems in parents, criminal behavior in fathers, inconsistent parenting), child factors (e.g., difficult temperament, early behavioral problems, low IQ), and community factors (e.g., socioeconomic disadvantage, delinquent peers, and a poor school

environment; Jain n.d.). Additionally, individuals with ASPD may have a higher threshold for stimulation and an underlying hypoarousal condition, which may drive them towards reckless, destructive, and impulsive activities (see Hashmani 2018). Unlike Cluster A PDs, researchers have conducted clinical trials on Cluster B PDs; however, evidence for effective treatments remain limited (Meloy and Yakeley 2014). Most treatment programs adhere to the risk-need-responsivity model, where the focus is on risk (targeting those at greatest risk of offending), need (criminological risk factors, i.e., criminal attitudes, substance abuse, impulsivity), and responsivity (maximizing offender engagement in the treatment process; Meloy and Yakeley 2014).

It is important to note that all PDs originally emerged and continue to persist through natural selection for a purpose – they present some sort of adaptive benefit or advantage. Although ASPD symptoms may be detrimental to society, they may yield benefits for the individual, at the cost of others (Hashmani and Jonason 2017). Moreover, life history theories (Frankenhuis and Giudice 2012) and an evolutionary developmental mismatch approach (Cameron et al. 2005) explain the emergence of these behaviors by suggesting that natural selection favors antisocial behaviors and increases fitness adaptability for individuals who engage in such a lifestyle (see Hashmani and Jonason 2017). Furthermore, psychopathy, for instance, consists of an inability to create close connections with others (negative trait); however, on the other hand, these individuals experience a lack of “normal” emotions (e.g., guilt, shame, empathy), which can be disabling and mentally exhausting (positive trait), and can assist in depersonalizing oneself from the victim in order to commit crime (positive trait; Hashmani and Jonason 2017; Hashmani 2018). The purpose of this chapter is to provide an understanding of the ten PDs and the need for standardized treatment; however, the author urges readers to consider the adaptive and beneficial aspects of PDs, rather than stigmatizing and pathologizing such conditions.

Borderline personality disorder. Borderline personality disorder (BPD) is a pattern of

impulsivity, as well as instability in interpersonal relationships, self-image, and affects (see Table 5; American Psychiatric Association 2013). Prevalence rates of BPD include 1–2% of the general population, 10% of outpatient populations, and 20% of inpatient populations (Lieb et al. 2004). Sex differences vary greatly, as BPD is more common in females than males (70–30%, respectively; Lieb et al. 2004). Comorbid PDs are paranoid, avoidant, and dependent, as well as other diagnoses, such as major depressive disorder, substance use disorders, post-traumatic stress disorder, anxiety disorders, eating disorders, and bipolar disorder (Lieb et al. 2004).

Causal factors for BPD follow a biosocial theory model (Linehan 1993) where the integration between biological/genetic factors and environmental factors leads to the development of BPD symptomology. Genetic factors illustrate abnormalities in the frontal limbic network, the prefrontal cortex, the hippocampus, the amygdala, and an inadequate role in serotonergic neurotransmission, which may be associated with disinhibited impulsive aggression (Lieb et al. 2004). Moreover, weak prefrontal inhibitory control could contribute to amygdala hyperactivity – a common factor in individuals with BPD (Lieb et al. 2004). Furthermore, adverse childhood experiences (e.g., neglect, sexual abuse) may cause emotional dysregulation and impulsivity, leading to harmful behaviors and psychosocial conflicts (Lieb et al. 2004).

Unlike the other PDs discussed in this chapter, BPD has a treatment method with empirical support proving benefits in those that follow the treatment plan (Shearin and Linehan 1994; Linehan 1993). This method, dialectical behavior therapy (DBT), aims to target individuals' interpersonal, self-regulation, and distress tolerance skills, while emphasizing the importance of mindfulness practices (Shearin and Linehan 1994; Lieb et al. 2004; Linehan 1993). Key areas that DBT targets include teaching individuals the skills needed to tolerate emotional distress, increasing effectiveness in interpersonal conflicts, improving motivation to change, and structuring the environment in order to reinforce skillful behavior (Lieb et al. 2004). The focus of DBT is to offer an explanation of the biosocial theory in order to facilitate an

understanding of why one may be presented with this diagnosis, while also providing numerous skills to reduce its destructive impact on individuals' daily functioning.

Histrionic personality disorder. Histrionic personality disorder (HPD) is a pattern of excessive emotionality and attention seeking (see Table 6; American Psychiatric Association 2013). Prevalence rates of HPD range from 1% to 3% of the general population, and similar to the other PDs discussed, HPD occurs more frequently among inpatient populations (Mullins-Sweatt et al. 2011). There is mixed evidence on sex differences within HPD literature, as most studies suggest that males and females receive the diagnosis at the same rate, while other studies support a higher prevalence rate for females (see Mullins-Sweatt et al. 2011). The latter perspective is not surprising, as expressing emotions is more widely accepted in females than in males, given social norms. Common comorbidities are with other Cluster B PDs (antisocial and borderline), and somatization disorder (i.e., hysteria); moreover, the association between ASPD and HPD may be sex-typed versions of the same condition, where males and females present with the same symptoms, but males receive the former diagnosis, whereas females receive the latter (Lilienfeld et al. 1986; Sutker and Allain 2002).

Regarding the etiology of HPD, research suggests that having a genetic predisposition towards impulsivity or sensation seeking (similar to the hypoarousal condition discussed for ASPD), in addition to a severe maladaptive variant of extraversion (e.g., excitement seeking) and neuroticism (e.g., angry hostility), may lead to HPD behaviors (Mullins-Sweatt et al. 2011). Aside from biological factors, the tendency for families to emphasize, value, or reinforce attention seeking in an individual with such a genetic predisposition may lead to the development of HPD (Mullins-Sweatt et al. 2011). Risk factors for HPD include flamboyant, flirtatious, and attention-seeking behaviors in adolescence (Mullins-Sweatt et al. 2011). Additionally, these individuals may fall in love quickly, but become attracted to another person just as fast (Mullins-Sweatt et al. 2011). Their employment histories are erratic, often

complicated by their tendency to become romantically or sexually involved with clients, as well as by their affective instability, suggestibility, and impulsive decisions (Mullins-Sweatt et al. 2011). Although there is no specialized treatment for HPD, CBT aims to counter the individual's assumptions surrounding their need for attention by focusing on current and past relationships (Mullins-Sweatt et al. 2011). Moreover, group therapy is often used for HPD in an attempt to reduce attention-seeking behaviors. More specifically, the HPD individual may want the exclusive attention of the therapist, and group members may confront the individual, promoting a reminder of appropriate behaviors (Mullins-Sweatt et al. 2011).

Narcissistic personality disorder. Narcissistic personality disorder (NPD) is a pattern of grandiosity, need for admiration, and lack of empathy (see Table 7; American Psychiatric Association 2013). Prevalence rates of NPD are relatively low, including less than 1% of the general population, but range from 2% to 16% of clinical samples, and ultimately, the majority of those diagnosed are male (Campbell and Baumeister 2006; Widiger and Bornstein 2002). Comorbid PDs include paranoid, antisocial, borderline, and histrionic (Widiger and Bornstein 2002). Other comorbid diagnoses include substance use disorders (as substances may enhance grandiose self-experiences), depression or dysthymia, eating disorders, and the bipolar disorder spectrum (Ronningstad 2011; Campbell and Baumeister 2006).

Research suggests that an unempathetic, neglectful, inconsistent, and devaluing parental style (where attention and love from parents are contingent on success) is a strong risk factor for the development of NPD (Widiger and Bornstein 2002). Here, the child may have believed the parents do not love them for who they are, but instead for their accomplishments, creating the perspective that their self-worth is dependent on continued recognition of achievements (Widiger and Bornstein 2002). Treatment of NPD is most strongly inhibited by individuals' reluctance, as the process may insult their self-esteem by bringing up problems, imperfections, and shortcomings

(Ronningstad 2011). If an individual seeks treatment, it is often due to an acute crisis caused by personal failures, in response to ultimatums from others, an increasing sense of meaninglessness in their own life, or a loss of outside sources for narcissistic gratification (Ronningstad 2011). Although there is no concrete treatment method, the most common approach is based on CBT insights (Campbell and Baumeister 2006). The goal of this approach is to moderate one's narcissistic cognitions that accompany current manifestations, such as grandiose self-views, lack of empathy, and reactance to negative feedback (Campbell and Baumeister 2006).

Cluster C

Avoidant personality disorder. Avoidant personality disorder (APD) is a pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation (see Table 8; American Psychiatric Association 2013). Prevalence rates of APD range from 2.1% to 2.6% in the general population and approximately 3.6% in outpatient populations (Rettew et al. 2015). In regards to sex differences, research on the rates of diagnoses between sexes are said to be equal (Rettew et al. 2015). Dependent PD is the most common comorbid PD; however, the majority of the literature (Turner et al. 1992; Holt et al. 1992) addresses APD in combination with various types of social phobias and social anxieties, as there is great overlap between these conditions. Therefore, anxiety disorders are the most common comorbid diagnoses, although mood disorders are also likely to be presented alongside APD (Holt et al. 1992; Widiger and Bornstein 2002).

Causes of APD include biological factors (e.g., heightened sympathetic reactivity to environmental change), as well as environmental factors (e.g., emotional or physical abuse) that transform the genetic predisposition into long-standing behavioral patterns (Alden 1989). Along with most PDs, there is no specific treatment protocol for APD. However, studies have demonstrated the use of skills training as a treatment approach, which focuses on the development of intimate relationships while teaching individuals to monitor

others' comments and emotions, to express empathetic concern, and to engage in appropriate self-disclosure (Alden and Capreol 1993). Additionally, graduated exposure, a regimen targeted towards mastering progressive relaxation techniques, increasing satisfaction with social activities, and facilitating individuals to approach social situations may yield benefits for those with APD (Alden and Capreol 1993).

Dependent personality disorder. Dependent personality disorder (DPD) is a pattern of submissive and clinging behavior related to an excessive need to be taken care of (see Table 9; American Psychiatric Association 2013). Prevalence rates of DPD range from 0% to 7% among outpatient populations, but are much higher among inpatient populations with approximately 15–25% diagnosed; moreover, females are diagnosed more often than males (Bornstein 1997). DPD has high rates of comorbidity with other PDs, such as schizoid, schizotypal, borderline, histrionic, narcissistic, and avoidant. Moreover, DPD is comorbid with many other diagnoses, such as eating disorders, anxiety disorders, and somatization disorder (Bornstein 1995).

Causes of DPD suggest that behaviors follow the onset of physical or physiological illnesses, as the illness causes the individual to feel vulnerable, frightened, and helpless, and seek the support of others; thus, showing an increase in overt dependent behavior (Bornstein 1995). Additionally, parental overprotectiveness and authoritarianism may reinforce dependent behaviors in childhood and prevent the child from developing independent, autonomous behaviors (Bornstein 1992; Faith 2009). Consistent with most PDs, there is limited research on treatment approaches; however, psychodynamic therapy attempts to help individuals better cope with object losses and/or previous separations (Faith 2009). Moreover, CBT is used to increase one's autonomy and self-efficacy while challenging dichotomous beliefs, such as the need to be either dependent or independent, with no in-between (Faith 2009).

Obsessive-compulsive personality disorder. Obsessive-compulsive personality disorder (OCPD) is a pattern of preoccupation with

orderliness, perfectionism, and control (see Table 10; American Psychiatric Association 2013). Prevalence rates of OCPD are approximately 2–8% of the general population, and it is considered to be the most common PD in the general population as well as among outpatients (Pinto 2016; Diedrich and Voderholzer 2015). Evidence on sex differences indicate mixed results, with some studies showing equal prevalence among males and females, while others demonstrate higher rates of OCPD in males (Diedrich and Voderholzer 2015). Common comorbid PDs include paranoid, schizotypal, and avoidant, while other comorbidities include obsessive-compulsive disorder (OCD), impulse control disorders, eating disorders, substance use disorders, and bipolar disorder (Abramowitz et al. 2008; Diedrich and Voderholzer 2015).

Causes of OCPD include biological factors, such as performance deficits in frontal executive functioning, resulting in obsessive-compulsive traits and impulsivity, as well as reduced gray matter volume in the limbic cingulate (Abramowitz et al. 2008; Diedrich and Voderholzer 2015). Additionally, research suggests that OCPD individuals never formed secure attachments, experienced more overprotection during childhood, and failed to develop emotionally and empathetically – all risk factors for the development of OCPD (Diedrich and Voderholzer 2015). There is very limited research on the treatment of OCPD; however, a case study showed potential benefits by using CBT to focus on clinical perfectionism, as well as skills training in emotion regulation and relationship flexibility (Pinto 2016). Other studies support the use of CBT models targeting dysfunctional cognitions, lack of appropriate contingencies, negative affective dispositions, and issues relating to attachment and identity (Kyrios 1998).

As a final note about OCPD, it is important to differentiate between obsessive-compulsive personality disorder (OCPD) and obsessive-compulsive disorder (OCD), an anxiety disorder. For instance, perfectionism is an OCPD criterion, but can be a symptom of OCD if it involves the need for order, symmetry, and arranging

(Abramowitz et al. 2008). Although there is great overlap between the symptoms of both disorders, there are qualitative differences in regards to the motivation to engage in such behaviors (Abramowitz et al. 2008). For example, if one's motive to complete a behavior is to avoid harm, they are likely presenting with OCD symptoms, whereas if one's motive is driven by feelings of incompleteness, they are likely presenting with OCPD symptoms (Abramowitz et al. 2008).

Conclusion

To conclude, the author has discussed the ten PDs according to the DSM-5 (American Psychiatric Association 2013). The purpose of this chapter is to raise awareness on the need for research on Cluster A and C PDs, and the need for empirically supported treatment methods. Thus far, Cluster B PDs (primarily antisocial and borderline) have received the majority of academic attention and research, while the remaining PDs have received scant attention, and very little is known about their etiology and treatment approaches. As clear support for this position, borderline personality disorder is the only PD with a specialized treatment plan – dialectical behavioral therapy. Additionally, the author encourages readers to consider the adaptive benefits of PD traits, rather than simply stigmatizing these behaviors and deeming them harmful. In order to outline the ten PDs, the author reviewed the following areas: diagnostic criteria (see Tables), prevalence rates, sex differences, comorbid conditions, causes and/or risk factors, and treatment approaches. Future researchers should target Cluster A and C PDs and strive to better understand these conditions and their reasons for emerging in evolution, while implementing clinical trials towards specialized treatment approaches.

Definition

Research that uses perspectives from evolutionary biology to examine ultimate-level explanations for mean sex differences in personality traits, and whether the size of these sex differences vary according to cultural factors that are of interest to biologists (e.g., environmental harshness versus prosperity).

Introduction

There are biological differences between the sexes (Del Giudice et al. 2016; Hines 2011) and such differences, intertwined with culture, can account for mean-level differences in how men and women behave, their personality traits, cognitive and coping styles, and the ways in which they initiate and maintain relationships and form groups with others. Such differences can shape how men and women interact with the world and how people respond to them. In turn, although there are many similarities between men and women, sex differences have the potential to influence important social outcomes and may be particularly relevant to interactions between men and women in which one sex interacts with a member of the other sex at the extremes of a personality or behavioral trait. This entry consolidates knowledge on mean-level sex differences in personality traits and the extent to which these differences change across cultures and may be particularly

relevant at certain points in the lifespan. Evidence for differences between men and women in their social focus and coping styles are also discussed and the potential for these differences to influence important social outcomes (e.g., mental well-being). First, the entry outlines the importance of studying personality from a Darwinian perspective.

Personality and Darwinian Fitness

Differences between individuals in their personality and how they initiate and maintain relationships and form groups (i.e., their sociality) can have meaningful consequences for reproductive fitness in both humans and nonhuman animal species (reviewed in Nettle and Penke 2010; Seyfarth et al. 2012; Wolf et al. 2007). For example, personality traits related to risk-taking such as boldness and aggressiveness are measurable in nonhuman animals. Traits such as these are observed in nonhumans in environments in which low expectations for the future promote greater risk-taking (Wolf et al. 2007), which has parallels with evolutionary perspectives on human risk-taking in harsh environments (Daly and Wilson 2005). Other work has observed relationships between personality and reproductive fitness in human societies. For example, in polygynous societies in Senegal, female neuroticism and male extraversion are positively related to offspring quantity (Alvergne et al. 2010). Many Darwinian explanations are theorized for sex differences in temperament, personality, and sociality. To highlight one example, sex differences in direct (i.e., violent) aggression and risk-taking are explained in light of sexual selection theories. Here, sex differences both in physical strength and parental investment result in high cost and low reward from violent behavior or risk-taking by the sex that bears offspring (human females) in comparison to the sex that competes for access to mates (human males; Archer 2009; Campbell 2013). The following section consolidates knowledge on sex differences in personality at the trait level.

Sex Differences in Personality Traits

Although differences in traits and behaviors are more substantial *within* a given sex than between the sexes (i.e., the sexes still overlap on traits even when differences are observed between them), large-scale cross-cultural research suggests that there are reliable average differences in men’s and women’s responses to trait personality inventories such as the NEO-PI-R (Costa and McCrae 1992). For example, women, on average, score higher than men do on the trait dimensions of neuroticism (e.g., anxiety and vulnerability), agreeableness (e.g., altruism), warmth, and openness to feelings (Costa et al. 2001, see Table 1). Men, conversely, score higher than women do on the trait dimensions of assertiveness, openness to ideas, and excitement seeking (Costa et al. 2001). Meta-analytic reviews of the literature on impulsivity demonstrate that women are more sensitive to punishment than men are, whereas men are more prone to sensation-seeking both when measured via self-report and with behavioral measures of risk-taking (Cross et al. 2011). This same review also finds similarities between men and

women on other dimensions; whereas women are more sensitive to punishment than men are, there are no sex differences in sensitivity to potential reward (Cross et al. 2011). In other work, small but robust sex differences are observed on some dimensions of narcissism such as a tendency to exploit others and preferences for leadership or authority roles, where men score higher on these dimensions than women do (Grijalva et al. 2015). Collectively, there are reliable differences between men and women on some personality traits.

Sex differences in personality traits and temperament appear to emerge through early development. For example, among children between the ages of 3 months and 13 years, girls score higher than boys do on measures of inhibitory control and awareness of small changes in the environment (i.e., perceptual sensitivity), whereas boys score higher than girls do on measures of surgency, such as approach, laughter, impulsivity, and traits denoting extraversion, such as low shyness. Within these measures of surgency, boys score higher than girls do when reporting preferences for activity and high-intensity pleasure, which is consistent with active rough-and-tumble play styles observed more in boys than girls (reviewed in Else-Quest et al. 2006). Of note, these authors find no sex differences in measures of negative affect, which may point to the role of puberty and development in sex differences in neuroticism reported earlier. Sex differences in the personality traits discussed here, and their emergence during development, are of interest to scientists who formulate ideas about behavior with reference to an evolutionary perspective.

Although these analyses and reviews suggest evidence for sex differences in temperament and personality traits, other large-scale studies suggest that, in contrast to the small effect sizes for sex differences observed in the personality literature, more substantial sex differences are observed in men’s and women’s interests and proclivities (summarized in Table 1). For example, when analyzing large representative datasets of information collated from over four decades of interest inventories, which are used to inform an individual’s plans for their education and career, there are large

Personality, Gender, and Culture, Table 1 Snapshot of effect sizes for differences between men and women in interests, temperaments, and personality traits (Data from ^aCosta et al. 2001; ^bCross et al. 2011; ^cElse-Quest et al. 2006; ^dSu et al. 2009; ^eVoyer and Voyer 2014). Negative effect sizes indicate females score/perform higher than males do on the given dimension

Trait	Effect size (Cohen’s <i>d</i>)
Neuroticism (anxiety) ^a	−0.40
Neuroticism (vulnerability) ^a	−0.44
Agreeableness (altruism) ^a	−0.43
Assertiveness ^a	0.19
Openness to ideas ^a	0.32
Excitement seeking ^a	0.31
Sensitivity to punishment ^b	−0.33
Sensation seeking (self-reported) ^b	0.41
Inhibitory control (children) ^c	−0.41
Preference for activity (children) ^c	0.33
Interest in things versus people ^d	0.93
Educational advantage (languages) ^e	−0.73

sex differences in men's interest in "things" versus women's interest in people, whereas there are negligible sex differences in interests in working with data versus ideas (Su et al. 2009). To illustrate the former large *difference* and the latter *similarity* between men and women, the difference in interest in things versus people represents only a 46.9% overlap between men and women, whereas the similarity among men and women in their preference for data versus ideas represents a 92.3% overlap between the sexes. Consistent with the notion that sex differences are most apparent at the extremes or tails of a distribution, when Su and colleagues analyzed responses from the top 25% of individuals in the population, the ratio of females to males on the things-people dimension was 0.29. In other words, of those with a particularly *strong* interest in "things" nearly seven out of ten individuals within that population were male. These data demonstrate that men, on average, are more interested in things, gadgets, and environments, whereas women, on average, are more interested in conventional careers or careers with an artistic or social element to them. Sex differences in interests and proclivities may inform differences in social outcomes such as occupational choice, which is consistent with analyses that suggest that choice (whether free or constrained) plays a contribution in gendered occupational outcomes (Ceci and Williams 2011; Robertson et al. 2010). Interactions between temperament, environment, and interests may also inform other gendered social outcomes such as educational attainment. For example, girls have an average advantage in educational attainment that is large for language courses and negligible for maths courses (Voyer and Voyer 2014). The following section outlines some of the evidence for sex differences in sociality and associated relationships with important social outcomes such as well-being.

Sex Differences in Sociality and Social Outcomes

As men and women navigate their environment through time, sex differences in personality traits,

interests, and how we initiate and maintain relationships may contribute to sex differences in a variety of outcomes that are important from an evolutionary perspective. Indeed, the era of "big data" may play an important role for future research in this area. For example, researchers can analyze large "real-world" data sets from social networks and behavior online. To illustrate with one example, computer algorithms that analyze "likes" and "dislikes" expressed over social media can classify the sender of the like or dislike by their sex with a high degree of accuracy (93%, Kosinski et al. 2013). Moreover, analyses of behavioral displays online (e.g., self-selected profile pictures) suggest that women favor dyadic relationships with a few close friends, whereas men favor larger all-male groups or "cliques" (David-Barrett et al. 2015). These findings are interpreted as evidence that women favor quality in their social relationships (i.e., emotional closeness) over quantity of social relationships. Of note to evolutionary researchers, recent large-scale studies of this nature suggest that men's and women's social focus changes across the life course in ways that may influence reproductive fitness. Analyses of mobile phone datasets suggest that the sex difference in the quality versus quantity of relationships reverses around a person's late thirties, when women have more social contacts than men do. Presumably, these contacts function for gaining social or emotional support, whereas men's reduction in social contacts around this time may reflect a change in social focus from investment in attracting a mating partner to investment in paternity (Bhattacharya et al. 2016).

Consistent with differences in men's and women's social focus, and with the importance of emotional closeness in obtaining support from others, women are more likely than men to seek emotional support from others to cope with problems (Tamres et al. 2002). Sex differences in sociality may interact in complex ways with men's and women's temperament, cognitive styles, traits, and proclivities and with circumstances they encounter through the life course, to have cumulative effects on health or well-being. For example, the extent to which someone internalizes versus externalizes problems they

encounter is related to mental health concerns. Whereas internalizing is a predictor of the prevalence of mood and anxiety disorders, externalizing predicts the prevalence of antisocial personality traits such as substance use disorders (Eaton et al. 2012). Representative data from American samples demonstrate a sex difference in the lifetime prevalence of these disorders, such that being female reduces the odds of having an antisocial personality disorder ($OR = 0.63\text{--}0.84$) but increases the odds of having a mood disorder ($OR = 1.16\text{--}1.47$; Eaton et al. 2012). Potentially consistent with the sex differences discussed in risk-taking and social focus, in which males are greater risk-takers and less focused on emotional closeness and emotional support, being male is an important predictor of a suicide attempt compared to simply communicating suicidal ideation ($OR = 1.9$; Nock and Kessler 2006). As some researchers conceptualize suicidal ideation as a means to gain support from others in adverse circumstances, further work could examine the interplay between men's and women's sociality and important social outcomes related to health and mental well-being.

Culture, Development, and Caveats

Large-scale studies have examined the extent to which sex differences in personality are universal, or vary systematically according to various factors at the national or regional level. Some of these studies test evolutionary explanations for cultural variation in behavior against social role theories (see, e.g., Hyde 2014), according to which sex differences are theorized to be explained via socialization or exposure to culture (e.g., Western media) or structural factors that constrain opportunities for one sex to the advantage of another. In contrast to social role theories of behavior, the size of sex differences in personality traits measured via the NEO-PI-R (Costa and McCrae 1992) are *larger* in more prosperous countries in which females have greater educational opportunities (Costa et al. 2001). Other analyses of data from over 50 nations indicate that across nations, men and women score differently on extraversion,

agreeableness, neuroticism, and sex-typical occupational preferences. Moreover, women are more *variable* in extraversion than men are, and men are more *variable* in agreeableness than women are (i.e., the distribution of self-reported scores is wider; Lippa 2010). When examining national variation in sex differences in personality traits, measures of gender equality and economic development used by the United Nations are associated with larger sex differences in agreeableness, suggesting that sex differences on this trait dimension are greater in more prosperous nations (Lippa 2010). However, when Lippa examined trait means for each of the four traits at the national level, only biological sex predicted these trait means and did so more strongly than did measures of gender equality. Findings such as these suggest that although the size of sex differences in personality vary with national prosperity, sex remains a more powerful predictor of personality, which researchers suggest is evidence for universality in personality (Lippa 2010). These findings complement other cross-cultural work indicating that women in a majority of nations score higher than men on some of the Big-Five personality traits, but the size of these sex differences are *greater* in nations that are better developed, according to measures for national health and wealth, and have gender parity in access to education (Schmitt et al. 2008).

Evidence for sex differences in personality traits or proclivities at the population level does not rule out the possibility that individuals vary in how they develop these traits over time or the possibility that traits and temperaments are expressed differently in certain contexts or at different points in the lifespan. Further longitudinal work in this area that tests hypotheses from an evolutionary perspective is warranted. For example, measures of social dominance orientation (a facet of extraversion), conscientiousness, and emotional stability increase between 20 and 40 years of age (Roberts et al. 2006). The size of the change in measures such as social dominance orientation is much greater in young adulthood (ages 18–22; $d = 0.41$) than it is during adolescence ($d = 0.20$), whereas changes on this dimension are minimal around the fourth decade

of life. Changes in personality traits or lack thereof are interesting if they correspond to an age period where competition for mating partners is particularly intense (see, e.g., references to work by Daly and Wilson throughout this encyclopedia). Further work examining short-term and long-term changes to traits such as social dominance orientation and the relationships of these changes to sex is likely to advance knowledge, given the observed relationships between biological sex and both direct aggression (Archer 2009) and indirect aggression (Vaillancourt 2013).

Finally, research on sex differences is sometimes controversial, particularly when individuals (mistakenly) interpret or disseminate scientific findings through a political lens. If sex differences exist on certain dimensions, they are important to understand and to gain insight into the choices and tradeoffs that people make and the subtle differences in the ways that men and women perceive the world. Such knowledge may enable us to maximize well-being or flourishing for both men and women. Moreover, knowledge of behavior at the group level does not necessitate the conclusion that we should treat individuals unfairly based on such knowledge. For an excellent overview of the social implications of evolutionary research on sex differences, and the conclusions or fears that do not follow logically from knowing more about sex differences, Pinker (2003) is highly recommended. People may also view sex differences as controversial simply from viewing this term as implying 0% overlap between men and women on a given trait dimension, which is rarely the case, as demonstrated both by common sense observation and the research reviewed here. Finally, it is worth noting that in research which demonstrates (in large samples) small but significant differences between men and women according to conventional effect size measures, these differences are still important to understand (*contra* Hyde 2014). For example, if we form stereotypes (or mental shortcuts) about people based on minimal information about them, interactions between two groups may still reinforce firmly held stereotypes if we overgeneralize about the

other group based on interaction with a member of that group who lies at the extremes of a particular trait.

Conclusion

Personality and sociality are important topics for evolutionary-minded researchers. There are reliable differences between men and women on some personality trait dimensions, such as components of neuroticism and agreeableness. The size of sex differences in personality appear to be larger in environments in which men and women are better able to pursue their own interests and proclivities (i.e., prosperous environments). Effect sizes in this area are larger when examining men's and women's interests than when examining differences in trait-level personality, demonstrating that even when average differences are observed, there is still overlap between the sexes on these dimensions. Men's and women's temperament, their cognitive and coping styles, and how they initiate and maintain relationships and form groups may shape gendered outcomes related to health, well-being, educational attainment, and career pursuit.

Definition

Peter Kropotkin (9 December 1842 – 8 February 1921) was a Russian author, activist, scientist, and philosopher.

Introduction

Peter Kropotkin was one of the great thinkers of the late nineteenth and early twentieth centuries. He wrote incessantly and what he wrote was read by many, both in the East and the West. And when he wrote and how much he wrote is nothing short of remarkable. On the run from the Russian secret police, in between two multi-year jail stints, and when he was not talking to crowds numbering at times in the thousands, Kropotkin authored books on: (1) evolution, behavior, and natural history (*Mutual Aid: A Factor of Evolution*, 1902), (2) ethics (*Ethics: Origins and Development*, 1924), (3) anarchism, socialism, and communism (*Modern Science and Anarchism*, 1908, *The Conquest of Bread*, 1913, and *The State: Its Historic Role*, 1903), (4) the coming industrial revolution in the East (*Fields, Factories, and Workshops*, 1899), (5) penal systems (*In Russian and French Prisons* and *The Terror in Russia*, 1887), (6) The French Revolution (*The Great French Revolution*,

1909), and much more. At first glance these topics may seem unconnected, but in fact, a common thread – Kropotkin’s biological law of mutual aid, which he argued guided all living things from microorganisms to nonhuman animals to humans – tied all of these works together (Kropotkin 1899b; Dugatkin 2011). What Kropotkin then called mutual aid, we now call cooperation.

Early Life

Born in Moscow in 1842 to a family that once were princes, in his teenage years he was the personal page to Czar Alexander II. During that same stretch of time, he also read Darwin’s *On the Origin of Species*. He came to think that evolutionary principles explained the diversity and history of life. Over time he would argue that natural selection was the driving force that shaped life, but that Darwin’s ideas had been perverted. Kropotkin’s theory of mutual aid was born in the most unlikely of places. To follow in the footsteps of one his heroes, Alexander von Humboldt, in 1862 when he was 20 years old, Kropotkin began a five-year series of expeditions in Siberia. He was already an evolutionary biologist, but 50,000 miles and 5 years later, when he left Siberia, he thought very differently about how evolution worked.

Mutual Aid and Siberia

When Kropotkin began his journey through Siberia, just 3 years after *On The Origin of Species* was published, competition was thought to be the driving force producing evolutionary change. Kropotkin expected to confirm what he had read on this. He searched for competition, nature “red in tooth and claw.” But no luck:

Even in those few spots where animal life teemed in abundance, I failed to find—although I was eagerly looking for it—that bitter struggle for the means of existence, among animals belonging to the same species, which was considered by most Darwinists (though not always by Darwin himself) as the dominant characteristic of struggle for life, and the main factor of evolution. (Kropotkin 1902)

Instead, Kropotkin observed cooperation and altruism – what he called mutual aid. Animals grouped together to stay warm, emitted alarm calls warning of danger, and shared what food they had. “In all the scenes of animal lives which passed before my eyes,” he wrote, “I saw mutual aid and mutual support carried on to an extent which made me suspect in it a feature of the greatest importance for the maintenance of life, the preservation of each species and its further evolution” (Kropotkin 1902). Kropotkin studied the human populations of Siberia as well as the nonhuman. He spent much time in the small villages scattered across the harsh landscape, recording acts of mutual aid among the individuals in these places.

How then to align his observations with the predominant Darwinian theme of competition? Kropotkin’s solution was this: natural selection was indeed the primary force shaping life, but this process led to mutual aid, not competition, among individuals. Many years later, he would summarize these ideas in his classic book, *Mutual Aid*. Natural selection, he proposed, generally led to cooperation and altruism – what he called mutual aid – not to individual versus individual competition. He came to speak of *progressive evolution*, a term he used to describe how mutual aid became the *sine qua non* of all societal life – animal and human.

Conclusion

Kropotkin was at least a century ahead of his time. While Darwin introduced the world to the idea of descent with modification, it was Kropotkin that first made the detailed, cogent case that studying animals sheds light on the evolution of cooperation. And if animals could cooperate in small, leaderless groups, Kropotkin believed, then surely we can as well, if we would just open our eyes to the lessons that nature teaches. He devoted much of his life to this cause. His overarching goal was to understand cooperation in nature, so that he could promote cooperation in humans. Just like in the animals he watched for 5 years in Siberia, Kropotkin saw human cooperation as ultimately being driven not by government but by groups of individuals spontaneously uniting to do good,

even when they have to pay a cost to do so. Time will tell if he is correct.

[Amputated limbs](#); [Phantom pain](#); [Phantom sensations](#)

Definition

Phantom limb refers to a vivid sensation and a perception of the physical existence of a limb that has been amputated.

Introduction

It has been widely suggested that many people who lose a limb to amputation, they have continued to sense intensely and in a vivid manner the existence of the lost limb a phenomenon that has been widely termed as “phantom limb” (Pinel and Barnes 2017). Over the last century, there had been numerous attempts to analyze theoretically, operationally, and religiously this striking phenomenon, varying from psychoanalytic hypotheses related to unconscious wish fulfillment to the postulation of an immaterial psyche (Daroff 2015). However, in the last few decades, a substantial amount of researchers have proposed that these phenomena are the result of neuroplasticity (Ramachandran 2012). The most remarkable characteristic of those phenomena is the incredibly realistic sensation and perception of it by the individual who is experiencing it. Specifically, people who continue to feel the presence of a lost limb might attempt to walk onto a missing leg or to lift a glass of water, using a missing hand (Ramachandran 1998).

It has been consistently cited in the relevant literature that an amputated hand and/or a leg is perceived to operate in the same way as an existing limb. For instance, when a person who lost an arm is walking, he/she sense the phantom leg to move back and forth in perfect synchronization with the physically existed arm. Yet, from time to time an individual might sense his/her lost limb stacked in an atypical posture (Ramachandran and Rogers-Ramachandran 2000). For instance, a person might feel that her/his missing arm extends straight-out from the shoulder. Consequently, she/he feels that he must turn and as a result, he is turning sidelong every time she/he passes through a door. Moreover, approximately half of the people who experience the phenomenon of phantom limbs experience

long-term and intense pain in their missing limbs (Ramachandran 2012).

For a long period of time, neuroscientists presumed that the cortical area matching to an amputated limb will become dormant, as axons in different cortical areas cannot sprout as far as to get to the cortical area corresponding to the amputated limb (Zillmer et al. 2008). However, surprisingly researchers in a study of the cerebral cortices of monkeys whose sensorial neurons from either one of their front limbs were cut 12 years before detected that the stretch of cortex formerly reacting to a limb that had been cut was now reacting to the face (Ramachandran 2012). Following the loss of sensorial information by either one of their front limbs, the axons that were responsible for it were gradually degenerating. Consequently, there were left unoccupied synaptic areas at numerous dimensions of the central nervous system (Pinel and Barnes 2017). One hypothesis is that axons that are responsible for the face were sprout inside areas in the spinal cord, brain stem, and the thalamus. A further hypothesis is that axons that are accountable for the face and were there came to be more powerful due to denervation supersensitivity. A substantial amount of research using magnetic resonance imaging verified that human beings respond to an amputation of a limb in the same way (Pinel and Barnes 2017).

Pinel and Barnes (2017) propose that in cases in which some of the areas of the brain lose some of their incoming axons, it is expected to be observed as an increase in the reactivity of the axons that have survived and collateral sprouting by axons which have typically other functional qualities. Additionally, every limb has a specific set of nerve cells which receives sensorial information from it. As already has been mentioned, in a significant number of cases of limb-amputation, it has been hypothesized that this set of cells is now receiving sensorial info from the face (Pinel and Barnes 2017). That is, following the amputation of a limb, a significant number of patients experience a vivid sensation of the lost limb when a specific area of the face is stimulated. Specifically, the etiology of the striking phenomenon termed as phantom limb seems to lie in the

anatomical structures of the brain (Daroff 2015). The whole layer of tissue forming the natural outer part that covers the body's left side is charted onto the strip of cortex that is termed postcentral gyrus which is located on the brain's right side (Zillmer et al. 2008). This chart is usually demonstrated with the animation of a human male arranged on the brain's uppermost layer. Although this chart is mostly precise, some parts of it have been scrambled in comparison to the accurate design of the human body (Pinel and Barnes 2017). Therefore, in case of a leg amputation, the leg does not physically exist, yet a mapped leg still exists in the anatomical structures of the mind. The operational function of this chart is to represent its leg. Following the amputation of the leg, this map continues to represent the leg something that gives an explanation related to the etiology of phantom limbs phenomena (Ramachandran 2012).

Conclusion

Medical doctors have consistently observed that a significant amount of individuals who lose a limb continue to perceive a vivid sensation of the limb that they have lost. Yet this phenomenon is not a homogenous one. Specifically, the phenomenon of a phantom limb could be manifested in various ways. For instance, it can vary from a sporadic tingles to severe painful sensations and from an infrequent to a continuous manifestation (Pinel and Barnes 2017). Additionally, it has been consistently observed that people can experience this phenomenon in every part of the body that has been amputated. Moreover, the experience of a sensation of a lost limb may be manifested for few days, months, or for the whole duration of an individual's life (Ramachandran 1998). Recently, neuroscientists have suggested that this striking phenomenon manifests when the pertinent section of the somatosensory cortex alters in the way in which it is organized and grow to be responsible to other inputs (Pinel and Barnes 2017). For instance, axons reflecting the face acquire the capacity to stimulate the cortical area formerly responsible for a leg that has been amputated.

Furthermore, long-lasting plasticity consists of a central adaptive mechanism in the evolution of the human species. That is, through the process of natural selection, the human brain is considered to have acquired the capacity to use learning so that to operate and control the direction of cerebral as well as perceptual phase transitions (Ramachandran 2012).

Phenotype Linked Fertility Hypothesis, The

Brian Mautz and Murielle Ålund
Department of Ecology and Genetics, Uppsala
University, Uppsala, Sweden

Definition

Male secondary sexual (attractiveness or competitive) characters signal male fertility to potential female mates.

Introduction

The phenotype linked fertility hypothesis (PLFH) posits that male attractiveness traits, such as extravagant plumage, courtship, or weapon-like appendages, function as honest signals of male fertility. Robert Trivers (1972) reasoned that generally higher mating rates and the corresponding potential in males to become sperm depleted imposes selection on females to avoid sperm limited males. Males with the most vigorous courtship are indicating their sexual competence and adequate sperm supplies. Correspondingly, any

physical trait that males possess enhancing the appearance of this vigor would be exposed to strong sexual selection and quickly exaggerated through mate choice. The PLFH has also been invoked as an explanation for the observation that many bird species, which tend to exhibit social monogamy, have offspring sired by males other than primary social partners. If paired with a male that does not have adequate sperm supplies or possess nonfunctional ejaculates, selection would favor females to identify and mate with more fertile males outside the primary pair bond to avoid a reduction in fecundity (Sheldon 1994). This would result in two measurable effects: (1) a positive correlation between attractiveness and ejaculate quality and (2) extra-pair offspring should be sired by more attractive males. The PLFH invokes direct benefits of acquiring competent ejaculates to females, rather than the more controversial indirect genetic benefits of acquiring superior genes from more attractive mates (Sheldon 1994; Mautz et al. 2013).

Predictions, Assumptions and Evidence

Biologists are interested in the connection between pre- and postcopulatory sexual selection as both episodes interact and will determine net selection strength acting on male traits (Birkhead and Pizzari 2002). The PFLH predicts that there will be a positive correlation between male secondary sexual characters (SSCs) and (some aspect of) ejaculate quality. A positive relationship, as predicted by the PFLH, suggests that postcopulatory processes reinforce or strengthen precopulatory processes. If females can identify males by some phenotypic trait that indicates a functioning ejaculate, then this selection will generate a correlation between male traits and ejaculates and a direct link between pre- and postcopulatory processes. This prediction is connected to the “handicap hypothesis” that provides a general explanation for why male SSCs function as reliable indicators of male quality (Zahavi 1975). Secondary sexual characters increase male conspicuousness, divert resources away from other functions, and thus increase the

risk of mortality and other fitness costs. Only those males that are in the highest condition can invest in exaggerating SSCs without the corresponding mating gains being negated by greater costs of investment. Hence, condition is an indication of a male's ability to convert energetic resources into sexual signals and ejaculates.

Constraints on Investment

The relationship between SSC and functional ejaculates might not be as simple as a positive relationship. Resource, developmental, and evolutionary constraints might limit investment in either trait and alter the co-evolutionary dynamics. Life history theory predicts that there will be trade-offs between traits that depend on the same resources and that are closely related to fitness. Energy utilized to generate attractiveness traits might reduce the available resources that can be allocated to traits impacting the quality or size of an ejaculate (Mautz et al. 2013). In this case, a range of relationships can potentially be observed. For example, a negative relationship might be observed if the resources used to enhance attractiveness prevent investment into traits that might enhance fertility such as testis size or maintenance. Hence, the relationship will more broadly impact both variation in resource acquisition and allocation strategies. A negative relationship might also be found regardless of acquisition or allocation strategies. Selection tends to eliminate genetic variation in traits closely related to fitness, fixing those mutations that increase expression in both traits. The only standing genetic variation remaining then are deleterious alleles that have negative ("pleiotropic") effects on the focal traits.

Current Evidence

The current evidence to support the link between male traits and ejaculate quality is weak. Body size and a range of other male traits have been linked to female fertility, fecundity, and parental care, but most of the effects were relatively small (Møller and Jennions 2001). More recently a meta-analysis of 38 studies across a range of species found no relationship between exaggerated male SSCs and specific aspects of ejaculate

quality including sperm swimming speed, number, or size (Mautz et al. 2013). However, there was a weak positive correlation between SSCs and sperm viability (Mautz et al. 2013) which is, arguably, more important to female fertility over other sperm traits. Two subsequent meta-analyses specifically tested the prediction that longer sperm are correlated with larger weaponry used in intrasexual competition. One using ungulates (Ferrandiz-Rovira et al. 2014) found a negative relationship between weaponry and sperm length. Another comparing a broader range of animal taxa found no relationship (Lüpold et al. 2015). As with studies of other animals, studies in humans show mixed results. Humans show a range of sexually dimorphic traits that have been associated with sexual selection. A recent review has highlighted the potential for the PLFH to function in humans in a range of traits including facial symmetry/attractiveness, height, and intelligence. The data are mixed and issues with quantifying different sperm traits hamper the ability to make any judgment on whether the PLFH is supported in humans (Jeffery et al. 2015).

Assumptions of the PLFH

Apart from the differing predictions made by life history theory on the link between male attractiveness traits and ejaculate quality, the ability to detect these relationships is hampered by several issues (Mautz et al. 2013; Jeffery et al. 2015). These issues revolve around quantifying and defining both male quality and ejaculate quality. The definitions of "quality" and "condition" remain subject to much debate in the evolution literature (as in Mautz et al. 2013) which has made them difficult to measure in evolutionary ecology studies.

The problem when trying to infer if there is a general link between mate choice for particular SSCs and male fertility or sperm quality is that there is no current consensus on how to measure these traits across animal species. There is no standardized way of measuring sperm quality and typical measures might poorly correlate with actual fertility (Birkhead et al. 2009). Different fields have traditionally used different methods both to extract and analyze ejaculates, and

sampled populations might differ highly between species. For example, human fertility studies are generally based on men suffering from sterility issues, while studies from animal breeding programs typically involve highly fertile individuals only. Moreover, different techniques to measure aspects of fertility tend to yield highly different results (Jeffery et al. 2015). Despite decades of research on this subject, there is surprisingly no real consensus on the definition of sperm quality and different criteria are often used across studies. Important components of ejaculate quality generally include sperm morphology, swimming ability, longevity, and metabolic performance, though nonsperm related aspect of ejaculates such as seminal fluid components or chemical interactions between sperm and genital tract fluids might also play an important role (Mautz et al. 2013; Birkhead et al. 2009).

Finally, the phenotype linked fertility hypothesis relies on the assumption that females risk being sperm limited and need to ensure fertilization of their eggs, therefore needing external cues about a male's fertility. It is unclear how common infertility and sperm limitation actually are in the wild (Mautz et al. 2013). Sperm limitation and the need of external cues to evaluate males' fertility statuses might only be really relevant in truly monogamous species. Females that mate multiply (a very common phenomenon in nature) should be able to obtain sufficient quantities of sperm from different males and to rely on mechanisms of sperm competition to ensure the fertilization of their eggs by high-quality sperm. Mate-compatibility might be generally more important than fertility per se, in which case molecular mechanisms of sperm selection within the female reproductive tract, using specific chemical recognition cues on sperm cells, should be of particular relevance.

Conclusion

The PLFH currently lacks broad empirical support. Better definitions of quality and condition,

both for SSCs and ejaculates, might more clearly outline how researchers can measure the relationship between pre- and postcopulatory traits. Typical laboratory studies do not constrain resources available to their study organism. Performing studies under constraining environments might assist in measuring the relationship. Finally, determining if and when female fitness is constrained by access to ejaculates or some particular aspect of ejaculate quality will assist in defining the context that will generate a relationship between SSCs and fertility.

Phenotypic Resemblance and Kinship Detection

Lisa DeBruine

University of Glasgow, Glasgow, UK

Many types of cues can correlate with genetic relatedness. Contemporary researchers categorize potential kinship cues in two main classes: contextual and phenotypic (reviewed in Penn and Frommen 2010).

Contextual cues include information such as spatial location, timing of association, mating history, and state-dependent association (e.g., during the hormonal state that characterizes recent childbirth), as well as interactions between such factors. For example, co-residence duration is generally positively correlated with measures of altruism and incest avoidance between siblings (Lieberman et al. 2003). However, individuals who have experienced maternal perinatal association (i.e., the close association between your mother and a newborn potential sibling) show high levels of altruism and incest avoidance towards that sibling and do not show effects of co-residence duration (Lieberman et al. 2007).

Phenotypic cues are physical cues that correlate with genetic relatedness, such as odor, vocal, and facial resemblance. For example, facial resemblance is a strong candidate cue for phenotypic kin recognition in humans (DeBruine 2002, 2004a, b, 2005; DeBruine et al. 2005, 2008, 2011; Krupp et al. 2008, Krupp et al. 2012; Watkins et al. 2011).

Experimental approaches, such as computer-graphic manipulation (Tiddeman et al. 2001) of facial resemblance, have largely focused on behavior towards unfamiliar individuals (e.g., DeBruine et al. 2008). This research has established that these computer-generated “virtual siblings” elicit more cooperation in economic games (DeBruine 2002; Krupp et al. 2008) and are perceived as especially trustworthy (DeBruine 2005; DeBruine et al. 2011), but this resemblance

does not enhance the attractiveness of other-sex faces as much as same-sex faces (DeBruine 2004a; DeBruine et al. 2011) and even decreases attractiveness in an explicitly sexual context (DeBruine 2005). However, some research using different computer-graphic techniques for creating resemblance has found that self-resemblance enhances the attractiveness of other-sex faces as much as own-sex faces (Saxton et al. 2009) or does not enhance cooperation (Giang et al. 2012).

Another area of work on facial resemblance focuses on the perceptual mechanisms for perceiving resemblance. For example, judgments of facial similarity map almost perfectly onto judgments of kinship (DeBruine et al. 2009; Maloney and Dal Martello 2006) and kinship judgments rely on information from the upper half of the face (Dal Martello and Maloney 2006). Additionally, inverting faces does not interfere with kinship judgments, suggesting kinship cues exist in featural but not configural information (Dal Martello et al. 2015).

Much research on phenotypic cues of parent-child kin recognition focuses on the theoretically compelling, but empirically controversial, extent to which children differentially resemble their parents and the extent to which such resemblance affects parental solicitude. Because mammalian paternity is always less certain than maternity, some have predicted that children should preferentially resemble their fathers (Johnstone 1997) or maintain an anonymous appearance (Pagel 1997). Although studies consistently find that people perceive newborns to resemble their fathers (Daly and Wilson 1982), early empirical evidence showing that young children did look more like their fathers than their mothers (Christenfeld and Hill 1995) was not supported by further studies (Alvergne et al. 2007; Bressan and Dal Martello 2002; McLain et al. 2000). Relatedly, the theoretically compelling hypothesis that men should have stronger responses than women do to phenotypic cues of relatedness has been supported by some correlational (Apicella and Marlowe 2004) and experimental work (Platek et al. 2002, 2003), but not by other experimental work (Bressan et al. 2009; DeBruine 2004b; Welling et al. 2011).

Research on odor cues to kinship has largely focused on odors associated with the major histocompatibility complex (MHC, a highly polymorphic region of the genome that codes for proteins involved in immune response, reviewed in Brown and Eklund 1994). In humans, almost all of this research has investigated mate choice or preference, rather than prosocial behavior (reviewed in Havlicek and Roberts 2009). Because of this limitation, it is difficult to determine whether MHC-related odors are associated with mate choice and preference because of their utility as a cue of kinship or because of their utility in signaling genetic compatibility (Roberts and Little 2008). Additionally, the findings for assortative versus disassortative preferences in this area are mixed, potentially because responses to MHC-related odors interact with other factors, such as facial appearance or relationship context (Havlicek and Roberts 2009).

Definitions

Philippa Foot was a British author and philosopher who is best known for her work in ethics, particularly her work developing *the trolley problem*. She died on her 90th birthday on October 3, 2010.

Introduction

Philippa Foot (née Bosanquet) was a British philosopher best known for her work on morality and ethics (Grimes 2010). She earned a bachelor's degree in philosophy, politics, and economics at Somerville College in Oxford, England, in 1942 and a Master's degree from the same institution in 1946. She worked as a researcher at the Royal Institute of International Affairs during the Second World War and began lecturing at Somerville College in 1947 (Grimes 2010). She became the first philosophy tutorial fellow at Somerville College in 1949 and vice-principal in 1967, a post which she later abandoned so that she could take up a variety of visiting professorships in the United States of America (O'Grady 2010). She became a professor of philosophy at the University of California, Los Angeles, in 1974 and retired in 1991 (Grimes 2010).

The Scholarship of Philippa Foot

In her early work, notably in the essays "Moral Beliefs" and "Moral Arguments" that were

published in the late 1950s, Foot argued that moral statements were essentially emotional expressions because they could not be assessed as correct or incorrect in the same way as factual statements (Grimes 2010). She also asserted that virtues like courage, wisdom, and restraint are essential to human existence and make up the building blocks of morality, a position known as virtue ethics (Grimes 2010). Virtue ethics is one of three major approaches in normative ethics (i.e., the study of ethical action), with the others being deontology (i.e., emphasizing rules as the foundation of morality) and consequentialism/utilitarianism (i.e., emphasizing the consequences of actions as the foundation of morality). Similarly, in her most recent book, *Natural Goodness* (published in 2001), she argued that morals are based in objective human needs that can be compared to the physical needs of plants and animals (Grimes 2010).

However, Foot is arguably best known for her 1967 essay "The Problem of Abortion and the Doctrine of the Double Effect," in which she discussed the moral distinctions between intended and unintended consequences and between the duty to do no harm versus the duty to help others, using a series of vexing examples (Grimes 2010). The ethical dilemma now known as *the Trolley Problem* was first outlined in this essay and has received the most attention of the examples Foot provided. The Trolley Problem involves a dilemma faced by the driver of a runaway trolley that is careering toward five workers. The driver faces the dilemma of whether to divert the trolley onto another track where only one worker is present, thus sacrificing one life to save five. Although the dilemma may seem an easy one – one life lost is preferable to five – Foot applied the same logic to a surgeon killing one patient to donate his organs and save five lives, which is considered morally reprehensible despite the result being the same. Later, Judith Jarvis Thomson created two variations of the Trolley Problem known as the loop variant, where a bystander must choose whether to throw a switch to divert the trolley (sacrificing one life to save five) or not to intervene at all, and the fat man variant, where a bystander must choose whether or not to throw an

obese man onto the tracks to derail the trolley and save five lives (Cathcart 2013).

Conclusions

The use of the trolley problem and its variants to study morality has become known as *trolleyology* (Cathcart 2013). The trolley problem has been used by many researchers from a diverse background of disciplines to show how moral reasoning changes according to slight variation in context (e.g., Bleske-Recheck et al. 2010). More broadly, the work by Philippa Foot has spawned into an important subdiscipline that informs the evolution of human morality through interdisciplinary research.

Definition

Contrary to ancient ethics, which focusses on how to live a happy life, modern morality is the study of which actions are right or wrong.

Introduction

What Is “Modern Morality”?

In a sense, the phrase “modern morality” is an oxymoron, a bit like “weapons for peace.” Weapons cannot be for peace and morality cannot be modern. One does not speak of a modern geometry in the sense that Pythagoras’s theorem no longer holds, and one does not speak of a modern morality in the sense that one should no longer love one’s neighbor. But of course one does speak of a modern geometry in the sense that some geometries are not Euclidean and there all sorts of hitherto-accepted relationships that no longer hold. And one can speak of a modern morality in the sense that old moral norms no longer hold. Think of gay relationships, for instance, and how these were castigated and how far we – at least some of us – have come on these issues. Truly, there is not much of a paradox here, because it has been recognized at least since the Greeks that when one makes moral claims – treat gays and lesbians like you treat straight people – one is combining two things. First, *ultimate moral principles*, like the idea that you should love your neighbor as you do yourself. Second, *factual claims*, like the idea that sexual orientation is something conferred on us and not chosen, and does not in itself lead to degenerate behavior like pedophilia. An awful lot of the change in morality is change in beliefs about the nature of things. There are many reasons to criticize Freud, but let us never cease to praise him for bringing us from the Dark Ages of thinking about the supposed facts of sexuality.

Let us therefore never forget the empirical factual elements in making claims in the name of morality, and consequently let us not forget that, in one very important sense, in talking about “philosophical foundations” we are not directly talking about these factual elements. That is the job of the empirical scientist, although perhaps also of the novelist and the poet. Preachers will think it is their job too, but I will leave this as an exercise for the reader.

I have just said “in one very important sense.” Is there another important sense? One where factual issues are important? Generally, philosophers

divide moral questions into two categories: substantive or normative ethics and metaethics. *Substantive ethics* is concerned with what one should do. To take Christianity as a system with an ethical component, the Christian is told one should love one’s neighbor as oneself (i.e., what one should do). “Lord, when saw we thee an hungred, and fed thee? or thirsty, and gave thee drink? When saw we thee a stranger, and took thee in? or naked, and clothed thee? Or when saw we thee sick, or in prison, and came unto thee? And the King shall answer and say unto them, Verily I say unto you, Inasmuch as ye have done it unto one of the least of these my brethren, ye have done it unto me” (Matthew 25: 37–40). *Metaethics* is concerned with *why* one should do what one should do (i.e., foundations). For the Christian it is generally answered that one should do what one should do because that is the Will of God. It is what He wants. There are well-known problems with the so-called divine command theory, but these are not our problems here. For the Christian, it all stops with God.

Naturalism

We can take it that, in a system like Christianity, empirical factual elements do not really enter into the philosophical foundations. That God exists is presumably a fact – or not. Either way, it is not an empirical fact. You do not discover God under the microscope or through the telescope. And what God wills is what God wills. One often finds Christians wrestling with the Book of Job where God’s behavior is very un-Godlike in respects and where, when He is challenged on this, He basically tells people to mind their own business: “Where wast thou when I laid the foundations of the earth? declare, if thou hast understanding” (Job 38:4). However, to raise the other important sense about morality and the empirical world, there is an influential school of thought – probably David Hume (1739–40) was its most celebrated exponent – that thinks that philosophical foundations must begin with the empirical world. This is the “naturalistic” approach to philosophy. Hume was a century too early. He was not an evolutionist. But, thanks particularly to Charles Darwin (1859) – who was much influenced by Hume in

thinking about both morality and religion (Darwin 1871) – today we are evolutionists, and despite all of the newspaper chatter otherwise, the vast majority of serious evolutionists are Darwinian evolutionists. They think the key to understanding organisms – and this includes humans in their thinking and their behavior – is Darwin’s mechanism of natural selection (Ruse 2006). More organisms are born than can survive and reproduce. This leads to a struggle for existence. In the struggle, on average, those with features that help in the struggle will be successful – they will be the “fit” – and over generations this will lead to change, but change of a particular kind, namely in the direction of adaptive advantage. Organic features, characteristics – including human thought and behavior – will be as if designed for the benefit of their possessors.

Substantive Ethics

So how does evolutionary naturalism cashed out for human nature – more generally it used to be known as human sociobiology and now as evolutionary psychology – apply and yield insights when applied to morality (Ruse 1986, 1988, 2009, 2012)? Start at the substantive level. A common misconception – metaphors like the “selfish gene” have not exactly helped – is that Darwinism promotes strife and conflict and selfishness. After all, if the name of the game is survival and reproduction, then to use an old phrase, it is every man for himself. Every woman too, because one thing about Darwinism is that if women could not hold their own with men, very quickly we would all be men! One way out of this conundrum is to suppose that selection can act for the benefit of the group as well as for the individual. Hence, although groups may fight it out, within the group – which could well be a whole society – individuals are going to aid each other. Treat your neighbor like yourself. However, although there are some prominent supporters of “group selection” – notably ant-expert and sociobiologist Edward O. Wilson of Harvard – generally it is not thought a widespread and effective mechanism of change (Wilson and Wilson 2007). It is too open to cheating. I help you by giving you one of my two units of value (food or some such

thing), but you do not help me and keep both of your units to yourself. I end with one unit and you end with three, and pretty soon your selfish nature will spread through the population and all kinds of help – often known as altruism – will vanish (Williams 1966). However, there are several individual-selectionist mechanisms thought active and promoting behaviors that in the human we would describe as (substantively) moral. These are mechanisms that show that cooperation can have reproductive benefits. One may not get all of the cake, but half a real cake is better than all of a missed or nonexistent cake. One mechanism is so-called reciprocal altruism (Trivers 1971). You scratch my back and I will scratch yours, or in a bigger population you throw your unit of help into the general pool and draw on the pool as you need it, for instance, when young or old or sick. Another mechanism is so-called kin selection where one helps relatives because in so doing you are passing on your own genes – your units of heredity – that you share with relatives (Hamilton 1964; Maynard Smith 1982). Note that no one is saying that, in any of these cases, humans would be conscious of what they were doing. One would think slightly crazy someone who suddenly stopped helping someone else because they learnt that they were adopted and not really a blood sibling or cousin. As sexual behavior shows only too well, nature gets its way best when the actor is unconscious of the consequences.

Kin selection (as well as reciprocal altruism) points to one way in which modern science – modern Darwinian science – might make us reconsider our substantive moral norms. If we are more likely to help relatives, then moral sentiments – simple adaptations just like hands and teeth, penises and vaginas – are going to track this. We will feel a greater moral obligation to help relatives than strangers. And we will feel a great moral obligation to help those who might someday help us, or to help those whose position we might someday find ourselves in. So love your neighbor as yourself will not in fact be quite the simple norm that guides not just our actions, but our moral feelings about things. (This is an important caveat. We often do things that we do not

think are moral. What are being talked about now are things that we do think are moral.) How might the simple norm be modified? Well, you would think you have the greatest obligation to your closest relatives and in particular to those relatives who might still reproduce – children first, then siblings, and perhaps parents but probably not. After that, nephews and nieces, and cousins, and so forth. Then, real neighbors and friends, and so on out in your own society. It does not mean that you will not feel obligations to strangers in strange lands, but they will be down the list.

Note one very important thing about the naturalist approach to substantive morality. The naturalist is not a preacher, trying to get you to mend your ways. “Don’t waste your money on Oxfam. Your kid at private college needs another video game.” What the naturalist is trying to do is to get you to recognize fully and openly what you already really believe! I say I am going to quit smoking, but does anyone other than me think that I am really going to quit smoking? The naturalist is saying that we may preach a good line about loving our neighbors – and perhaps we do sometimes visit the sick or those in prison – but by and large we do not believe what we are saying. More than this, we don’t believe that we ought to believe what we are saying. If you heard a colleague being praised for his or her great contributions to charity, and then learnt that their kids have to eat at church food kitchens and their only clothing comes from Good Will, you would feel a lot less than admiring – even though, dollar for dollar their money is probably helping more people than otherwise. Charity begins at home.

The naturalist will back up these insights, showing that they are not merely self-justification by a selfish-philosopher by pointing to what others have said. Although he may not have been an evolutionist, Hume spotted what was happening and what should happen.

In like manner we always consider the natural and usual force of the passions, when we determine concerning vice and virtue; and if the passions depart very much from the common measures on either side, they are always disapproved as vicious. A man naturally loves his children better than his nephews, his nephews better than his cousins, his cousins better than strangers, where everything else

is equal. Hence arise our common measures of duty, in preferring the one to the other. Our sense of duty always follows the common and natural course of our passions. (Hume 1739–40, pp. 483–484)

In his great novel, *Bleak House*, Charles Dickens (1853 [1948]) makes a similar point. He is withering in his contempt for the philanthropist Mrs. Jellyby, who devotes all of her attention to the wellbeing of an African tribe – the “Borriboola-Gha venture.” In so doing, she ignores the needs of her own children and husband, not to mention the needy members of her own society, notably Jo the crossing-sweeper.

Metaethics

What of the naturalist approach to metaethics? There are those like Edward O. Wilson who think that in some ways nature is, if not living, then at least a thing of value in itself (Wilson 1992). This is the kind of thinking that inspires supporters of the so-called Gaia hypothesis, which states that the world is a living thing, and hence something of value that we should respect and cherish. This is a view with venerable roots, going back through the Romantics at least to Aristotle. For thinkers of this ilk, therefore, the fact that something is natural is itself value-conferring. Wilson, like others who belong to this tradition – notably the nineteenth-century English polymath Herbert Spencer (1857) – see life’s history as essentially progressive and humans as the apotheosis of this process. Hence, for them, moral norms center on human wellbeing. Anything that speaks positively to this is moral. Anything that does not, is not. Wilson himself has been much engaged in the biodiversity issue, arguing that the destruction of the Brazilian rainforests is devastating on species and hence – for our sake – should be stopped. Others, like the philosopher Holmes Rolleston III (1994), argue that value extends more broadly. He would be against the destruction of the rainforests not so much for our sake, but for the sake of the trees themselves. They have value and hence have rights.

Most naturalists do not buy into this line of argument. In this respect, they would be with Descartes (1964) in thinking that the natural

world is the world of inert substance – what Descartes called *res extension*, in contrast to the world of thought, *res cogitans*. (Most naturalists, starting with Hume, would not agree with Descartes that only we humans have *res cogitans*. They would deny that animals are pure *res extensa*.) The point is that if the world is inert then it has no value and we should not expect natural selection to produce it out of nothing. Evolution is not essentially progressive and what has evolved is not necessarily what is good. Darwin's great supporter Thomas Henry Huxley made this point: "Man, the animal, in fact, has worked his way to the headship of the sentient world, and has become the superb animal which he is, in virtue of his success in the struggle for existence" (Huxley 1893, p. 51). Continuing:

For his successful progress, throughout the savage state, man has been largely indebted to those qualities which he shares with the ape and the tiger; his exceptional physical organization; his cunning, his sociability, his curiosity, and his imitativeness; his ruthless and ferocious destructiveness when his anger is roused by opposition.

But, in proportion as men have passed from anarchy to social organization, and in proportion as civilization has grown in worth, these deeply ingrained serviceable qualities have become defects. After the manner of successful persons, civilized man would gladly kick down the ladder by which he has climbed. He would be only too pleased to see "the ape and tiger die."

So what is the naturalist to say about metaethics? The empirical world gives you no value and yet there is nowhere else to go but to the empirical world. The answer has to be that there is no value! Yet, this cannot be so, because we have values. Normal people feel strong obligations to look after their own children. People who do not do so are moral monsters. The solution has to be that we think we have values, we have sentiments that convey value, but there are no objective values out there in the world. Hume again. His analysis of causation did not deny that we have sentiments of causation. Of course a fire burns you. But his analysis of causation also said that there are no causes out there. There is no objective cause between the fire and the pain. It is all a matter of constant conjunction, giving rise to ideas – something we supply in our minds. The same with

morality: There is no morality out there. It is something we supply in our minds. So in a sense, just as thinking that there is an objective causality is an illusion – we post-Darwinians would say an illusion put in place by our biology to make us fear the fire – so there is no objective morality – we post-Darwinians would say an illusion put in place by our biology to make us good cooperators or altruists, because cooperation is a good reproductive strategy. One additional tweak, however: If we didn't think that causation and morality were objective, were really "out there," before long we would start to ignore them. Why should I help my neighbor if there is really no need to do so and if I can pretend to help but get away with doing nothing? So, to use an ugly word, we "objectify" causality and morality, because our biology makes us do so, and our biology acts as it does because those of our would be ancestors who were fooled and acted accordingly survived and reproduced and those that did not, did not.

One final point: Could not it be that there really is an objective morality and that natural selection tracks it? After all, because something is produced by natural selection, it does not follow that it is an illusion. I see and hear the approaching train and so get off the tracks. The train is no illusion. So why not morality? The point is that in the case of the train, if natural selection starts playing tricks and offers alternatives – it is no train but an alluring naked person (the sex and orientation of your choice) coming towards you – you are more likely to end up dead than reproducing. In the case of morality, natural selection could have gone another way. There is no necessary progress to one end. Morality is not like causation, dealing with the physical world. It is dealing with the world of relationships and that introduces a measure of freedom. Darwin knew the score.

It may be well first to premise that I do not wish to maintain that any strictly social animal, if its intellectual faculties were to become as active and as highly developed as in man, would acquire exactly the same moral sense as ours. In the same manner as various animals have some sense of beauty, though they admire widely different objects, so they might have a sense of right and wrong, though led by it to follow widely different lines of conduct. If, for

instance, to take an extreme case, men were reared under precisely the same conditions as hive-bees, there can hardly be a doubt that our unmarried females would, like the worker-bees, think it a sacred duty to kill their brothers, and mothers would strive to kill their fertile daughters; and no one would think of interfering. Nevertheless the bee, or any other social animal, would in our supposed case gain, as it appears to me, some feeling of right and wrong, or a conscience. For each individual would have an inward sense of possessing certain stronger or more enduring instincts, and other less strong or enduring; so that there would often be a struggle which impulse should be followed; and satisfaction or dissatisfaction would be felt, as past impressions were compared during their incessant passage through the mind. In this case an inward monitor would tell the animal that it would have been better to have followed the one impulse rather than the other. The one course ought to have been followed: the one would have been right and the other wrong; . . . (Darwin 1871, pp. 73–74)

If you want an example where you do not have to turn us into hymenoptera (ants, bees, and wasps), then consider what we might call the John Foster Dulles system of morality. Dulles, the secretary of state under Eisenhower in the 1950s, hated the Russians. He knew also that they hated him. It was not just a feeling. It was a sense of morality. But he knew that the mutual hate meant that they had to get along, otherwise they would start fighting. So they cooperated. Same ends, different moral system leading to them.

Conclusion

So now we can draw our discussion to an end. It is not so much that we have a modern morality, or if we do it is not because of its philosophical foundations. The modernity of morality comes from our better appreciation of the empirical facts. But modern science does support a newly empowered naturalistic approach to moral understanding, and that is what philosophy is all about. So perhaps our title is not really so misleading after all. Darwinian evolutionary theory – call it evolutionary psychology if you will – leads to renewed understanding of what we really hold as our moral norms and the same science leads to a fresh

understanding of the foundations, or perhaps the nonfoundations, of moral claims. In a way it is all in David Hume. But it is brought up to date by Charles Darwin.

Zoological philosophy

Definition

Philosophie Zoologique, by early French biologist Jean-Baptiste Lamarck, was published in 1809. In this book, Lamarck developed the first complete theory of organic evolution, arguing that the incredible diversity of living material on the Earth came about through evolution and describing processes of evolutionary change that produced that diversity. Although the specific processes he proposed failed to find experimental confirmation in later years, the book has had considerable impact on the life sciences and social sciences.

Introduction

Fifty years before Darwin's *On the Origin of Species* was published, Lamarck developed the first complete theory of evolution of living organisms – the foundational “evolutionist thinking” step in biology (Mayr 1982; Hull 1988). Lamarck raised species transformation ideas first in an 1800 lecture and pursued them more extensively in his 1802 book *Hydrogéologie* (Corsi 1988), but their full development was not reached until the

Philosophie Zoologique (hereafter, *PZ: Zoological Philosophy* 1809/1963, translated by H. Elliot). Lamarck is widely known for the inheritance of acquired characters, the notion that offspring tend to inherit traits their parents acquired. Although the inheritance of acquired characters was central to his arguments, the view was not novel to him (Burkhardt 1977, 2013).

PZ had minor impacts on science and society upon its publication (Burkhardt 1977). It was criticized by Lamarck's contemporaries, most of whom advocated creationist/anti-evolutionary explanations (Gould 2002). Nonetheless, *PZ* soon had foundational influences on the development of evolutionary theory, particularly in England (Richards 1987). It was also the earliest major break from essentialist thinking that had dominated the life sciences for centuries, including Linnaean views of biological organization (Mayr 1982).

Zoological Philosophy: An Exposition with Regard to the Natural History of Animals

Lamarck's book comprised three parts. The first and longest part was on the natural history of animals. Across eight chapters, Lamarck described arrangement, classification, and characteristics of animal species and developed his evolutionary arguments to explain animal diversity. In Part II, Lamarck discussed the physical causes of life. These nine chapters covered key features of living material and notions of irritability and spontaneous generation on which his evolutionary theory was based. Part III dealt with the physical causes of feeling and behavior. In its eight chapters, Lamarck discussed the nervous systems of animals and notions related to animal behavior including sensibility, feeling, will, instinct, and intelligence.

In Part I, Lamarck described the classification schemes researchers used to understand the living world. He argued for a very old Earth and raised views that almost converged on Darwin's writings on species change 50 years later (though without introducing the idea of natural selection): “In the same climate, very different habitats and conditions at first merely cause variations in the individuals exposed to them; but in course of time the

continued change of habitat in the individuals of which I speak, living and reproducing in these new conditions, induces alterations in them which become more or less essential to their being; thus, after a long succession of generations these individuals, originally belonging to one species, become at length transformed into a new species distinct from the first" (PZ, pp 39). Lamarck explicitly ascribed evolutionary changes to naturalistic processes, ruling out supernatural explanations.

Lamarck then discussed classes of organisms (above the species level) increasing in complexity – this notion of an inherent tendency toward complexity was core to his evolutionary theory. Following this discussion, Lamarck raised his theory of evolution in detail, describing environmental change altering needs of organisms that cause them to change their behavior: "Now if the new needs become permanent, the animals then adopt new habits which last as long as the needs that evoked them" (PZ, pp 107). This argument stemmed from Lamarck's First and Second Laws of Nature. The First Law stated that the increased use of an organ leads to its strengthening whereas disuse leads to weakening. The Second Law stated that these use/disuse modifications of organs, if developed in both female and male parents, will be passed on to offspring – this was the inheritance of acquired characteristics. Thus, as long as environmental conditions modify the needs of organisms, those changed needs will drive changes in behavior, and these latter changes will drive changes in bodily structure. Over many generations and long time periods, the population gradually evolves, potentially becoming a new species. Part I concluded with classification and organization of extant groups of species, now viewed in light of evolutionary change. It interestingly described an evolutionary scenario by which humans evolved, including how that most complex human behavior – language – came to be.

Part II began with extended discussion about the material basis of living organisms, their organization and activity, and their evolutionary change over time. Although Lamarck made numerous references to "subtle," "vital," and

"nervous" fluids, it was clear that he viewed these as materially based, mechanical in their operation, and ultimately knowable to science. Later, Lamarck described the notion of *irritability* in the activity of animals, in which organs become primed to respond to environmental stimuli through natural buildup of fluids inside the tissues. When the right environmental conditions stimulate the animal, those organs contract in response. Rapid replenishment of fluids results in the irritability phenomenon, and these characteristics exemplify how animals become finely tuned to their local environments.

Late in Part II, Lamarck described the process of spontaneous generation, an essential plank in his evolutionary views. He argued that the simplest forms of animals and plants were continually being generated under the right environmental conditions. Spontaneous generation was coupled with the inherent tendency toward increased complexity that he argued characterized all living organisms. These processes, combined with the First and Second Laws (see above), were the material basis for the evolution of species over time. Toward the end of Part II, Lamarck began a discussion of features of "higher" animals that made complex behavior possible. These included a muscular system that generated sustained and repeated movements. Additionally, *feeling* was the product of nervous systems and approximated what we would now call an affective response to environmental stimuli. Part II ended with the notion of *intelligence* as distinct from, and less widely spread across animal species than, feeling. Intelligence was a central idea in Part III.

Part III of PZ was in some ways as important to the early development of behavioral and psychological theory as Part I was to the early development of evolutionary theory. Lamarck began with a continuation of his materialist view of behavior and action and the functions and structures of nervous systems. He developed ideas about instinct, intelligence, and volition that are still being debated today. For Lamarck, all animals with nervous systems possessed *physical sensibilities*, which were emotional responses to external stimuli. The evolution of nervous systems allowed greater adaptability to conditions, as nervous

systems released animals from the direct influence of environmental stimuli. Further, animals with more advanced nervous systems possessed *moral sensibilities* that stemmed from “ideas, thoughts, or acts of our intellect” (*PZ* pp 336). Lamarck viewed moral sensibility in animals, or an “intimate feeling of their existence” (*PZ* pp 346), as possibly having arisen in insects, but certainly occurring in birds and mammals.

Lamarck offered fairly sophisticated views of instinctive behavior as being “fixed tendencies displayed by animals in their actions” (*PZ* pp 350). Instinct was contrasted with will, found in any animals with nervous systems, and intelligence, found primarily in birds and mammals. Intelligence allowed animals to vary their habits in potentially adaptive ways, as it gave “them the faculty of calling up ideas” (*PZ* pp 359) independently of direct physical sensibility. Intelligence comprised four faculties: attention, thought (what today we would call representation, including creative use of ideas), memory, and judgment (today, reason). These ideas relate to views of Thomas Aquinas in the 1200s and were advanced six decades later by Darwin in his 1872 book, *The Expression of the Emotions in Man and Animals* (Malone 2009). Finally, Part III addressed ideas, signs, communication, and language, all topics Lamarck developed further in writings after *PZ*.

Conclusion

Beyond being the first complete theory of evolution, *PZ* was suffused with materialism, rather than the idealism that was then popular in philosophy and the early life sciences. His key evolutionary arguments included the following:

- Changes in the environment may elicit new needs in animals, causing animals to change their behavior.
- Continued use of a body part strengthens it; disuse weakens it. New habits over time can thus lead to heritable change in body structure.
- Changes in body structure can then generate new relationships with the environment and thus modify needs.

- There is spontaneous generation of the simplest living matter, and all living organisms have a tendency to increase in complexity over generational time.

In this framework, animals were in harmony with nature much of the time. However, once sufficient environmental change occurred, animals’ needs changed. Organisms “adapted” to the new needs through changes in habits, and use and disuse of organs related to those habits along with the inheritance of acquired characteristics reestablished harmony with nature (Mayr 1982; Corsi 1988). Lamarck had an awareness of deep time and argued for the centrality of gradual changes over geological time scales. Lamarck “replaced this static world picture by a dynamic one in which not only species but the whole chain of being and the entire balance of nature was constantly in flux” (Mayr 1982, pp 352).

There are major limitations to views raised in *PZ*, of course. Many of Lamarck’s arguments were insufficiently based on evidence (Hull 1988), unlike Darwin’s arguments 50 years later in *On the Origin of Species*. Lamarck also generated some clear predictions from his theory, but never tested them (Hull 1988). One reason he did not test his ideas likely stemmed from his deep history view – that evolutionary processes were so gradual there would be insufficient time to document them adequately (Gould 2002). He also believed the evidence for acquired characters was so obvious that no one doubted it. It was not until the late 1800s that the idea was seriously questioned and tested experimentally (and largely refuted). It is interesting, though, that by the 1990s, it became clear that the molecular and non-molecular bases of epigenetic inheritance were extending some of Lamarck’s ideas into new directions and deepening our understanding of development and evolution (Jablonka and Lamb 1995). Additionally, Lamarck’s idea of a tendency toward increasing complexity was long discounted, but recent empirical work lends some support to the notion (e.g., Adamowicz et al. 2008).

In terms of behavior, Lamarck raised several important ideas about motivation and emotion,

instinct, and intelligence, particularly in Part III of *PZ*. These ideas still have relevance to our science today. Lamarck viewed instincts as related to habits that evolved due to the needs of animals that depended upon environmental conditions, an ethological view preceding the field of ethology by over 100 years. His notion of intelligence providing animals the capability of varying their habits flexibly in the face of environmental problems suggests a cognitive view preceding the field of comparative cognition by over 150 years. His views regarding the use and disuse of organs (including the intellect) led him to argue for providing educational opportunities to all to decrease societal inequalities.

Will had no immediate role in evolutionary change for Lamarck, despite the caricature raised at his death by Georges Cuvier and carried down through the decades (Richards 1987; Gould 2002). Lamarck argued that animals lowest on the evolutionary scale, with minimal nervous systems and nothing resembling will, nonetheless faced the same tendency to increase in complexity and the same changes in needs with sufficient environmental change. Crucially, for Lamarck, all of biology and evolution was natural and so had a material basis, and this represented a sharp break with creationist and supernatural accounts (Burkhardt 1977). Lamarck was the “first to make a complete break with these essentialist impediments against evolution” (Mayr 1982, pp 328).

Phobias

Michael Dalili
University of Bristol, Bristol, UK

Synonyms

[Abnormal fears](#); [Irrational fears](#); [Obsessive fears](#)

Definition

Particular objects, places, situations, feelings, or animals that provoke extreme, overwhelming, and debilitating fear or anxiety out of proportion to, or in the absence of, any actual danger.

Introduction

Isaac Marks (1987) described phobias as an intense fear of objects or situations that is out of proportion to their danger, cannot be explained or reasoned away, is beyond voluntary control, and leads to avoidance of the feared stimuli. He distinguished phobias from typical fear, stating that phobias occur without any objective source of danger and can develop in response to nearly anything. Furthermore, he referred to the intense feeling of fear or anxiety experienced by phobic individuals when they encounter their feared stimuli as phobic anxiety. Therefore, unlike typically occurring fear, phobic fear is irrational and debilitating and is not adaptive. Most phobic or fear-relevant stimuli can be broadly classified into two categories: phylogenetic and ontogenetic stimuli. Phylogenetic fear stimuli are evolutionary-based stimuli that are typically common to all mammals and have posed threats throughout natural history, such as snakes, predators (e.g., tigers), and heights. Ontogenetic fear stimuli refers to feared objects or situations experienced during our life span that only recently emerged in our evolutionary history, such as guns, electric outlets, and flying. Phobias received their own diagnostic label as a mental disorder first in the International Classification of Diseases (ICD) in 1947 followed by the Diagnostic Statistical Manual of Mental Disorders (DSM) in 1952. Phobic disorders are classified among anxiety disorders, whose features include excessive fear and anxiety and related behavioral disturbances.

Phobic Disorders

Phobic disorders are the most prevalent of all the anxiety disorders and are among the most prevalent of all 12-month disorders (Kessler et al. 2005). These disorders, as classified in the DSM-5 (American Psychiatric Association 2013), consist of specific or simple phobia, social phobia (also known as social anxiety disorder), and agoraphobia. These disorders share a number of features and diagnostic criteria. To be diagnosed with a phobic disorder, the individual's fear or anxiety

must be intense or severe, these feelings must be evoked every time they come into contact with the phobic stimulus, and their response must differ from fears that commonly occur in the population. The individual's fear, anxiety, and avoidance behavior must interfere significantly with their daily routine and cause important impairment to their functioning. They will also show active avoidance to their phobic stimulus, where they behave in such a way to minimize or prevent contact with the specific phobic object or situation, otherwise enduring it with intense fear and anxiety. Finally, the individual's response must also be out of proportion to the actual danger that the object or situation poses. An important change in diagnostic criteria for phobic disorders in the DSM-5 is that an individual no longer has to recognize that their anxiety is excessive or unreasonable in order to receive one of these diagnoses. The following sections will briefly describe each disorder as specified in the DSM-5.

Specific Phobia

Specific or simple phobias are defined as intense and unreasonable or irrational fears of specific objects or situations. Approximately 75 % of individuals fear more than one situation or object, with the average individual fearing three or more objects or situations. The DSM-5 recognizes five categories of specific phobias: animal (e.g., spiders, insects, dogs), natural environment (e.g., heights, storms, water), blood-injection-injury (e.g., needles, invasive medical procedures), situational (e.g., airplanes, elevators, enclosed spaces), and other (e.g., situations that may lead to choking or vomiting; for children, loud sounds or costumed characters).

Social Phobia

Social phobia, also referred to as social anxiety disorder, involves the marked or intense fear of social situations where the individual may be scrutinized by other people. While up to a certain point social anxiety is normal and may facilitate functioning, moderate or severe levels result in impairment and dysfunction. The individual fears that their actions or behaviors will be negatively evaluated and that they may show

symptoms of anxiety such as blushing, trembling, or sweating. Individuals may also fear offending others, which may consequently lead to them being rejected. Individuals with social phobia may avoid feared situations where their symptoms may manifest themselves and cause them to be negatively evaluated.

Agoraphobia

Agoraphobia is characterized by intense fear or anxiety triggered by the real or anticipated exposure to a range of situations. To meet criteria for diagnosis, the individual must fear two or more situations. These include, but are not limited to, using public transportation, being in wide open spaces, being in enclosed spaces, standing in line or in a crowd, and being outside of the home alone. Fear or anxiety cued by the presence or anticipation of a phobic situation may include believing something terrible might happen, believing that help or escape from the situation is impossible, and experiencing panic-like, embarrassing, or incapacitating symptoms. Individuals with agoraphobia will actively avoid phobic situations both behaviorally (e.g., changing daily routines) and cognitively (e.g., using distraction to get through agoraphobic situations), sometimes resulting in the individual becoming homebound. Individuals with agoraphobia are likely to suffer from comorbid disorders and often experience panic attacks, with 30–50 % reporting panic attacks or panic disorder preceding the onset of agoraphobia. However, the DSM-5 no longer links panic disorder and agoraphobia, instead recognizing them as two separate disorders, as not all individuals with agoraphobia experience panic symptoms.

Developmental Theories of Phobias

One of the earliest theories of how individuals develop phobias was the preparedness theory proposed by Martin E. P. Seligman (1971). He suggested that evolution has helped shape an adaptive biological preparedness for humans and animals to learn to associate some stimuli with fear or threat more easily than other stimuli. He

specified that phobias comprise a relatively non-arbitrary and limited set of stimuli related to the survival of humans throughout the course of evolution, such as snakes, heights, and the dark. Seligman specified that phobias are instances of prepared conditioning of fear; that is, humans seem biologically prepared to easily acquire phobias to phylogenetic stimuli with biological and evolutionary relevance, compared to unprepared conditioned fears to fear-irrelevant or ontogenetic stimuli. In addition, he specified that phobias are selective and resistant to extinction and are non-cognitive or irrational.

However, empirical studies have offered mixed support for the preparedness theory (see McNally 2015). While studies did not find evidence of faster acquisition to biologically prepared fear cues, they did find that fear responses to these cues were both more resistant to extinction and noncognitive. Additionally, Seligman's interpretation of phobias faced some limitations. These included difficulty explaining phobias suffered by individuals who never had a negative conditioning experience (e.g., an individual suffering from a snake phobia who had never been bitten by a snake), that not all prepared stimuli for fear conditioning posed threats to humans historically (e.g., spiders), and that evolutionary significant fears may be sustained by the individual's avoidance of feared cues rather than being truly resistant to extinction (McNally 2015).

Since Seligman's classic theory, many others have emerged (see McNally 2015), with two recent theories briefly described here. Ohman and Mineka (2001) proposed an evolutionarily evolved fear module for fear learning and elicitation, a theoretical extension of the preparedness theory integrating findings from human, primate, and neuroscience studies. The module's characteristics are that it is activated by specific evolutionarily fear-relevant stimuli that often become the object of human phobias, it is automatically and involuntarily activated by such stimuli, it is encapsulated and therefore fear responses are impervious to cognitive control (contributing to the maintenance of phobic behavior), and it reflects the operation of a specialized neural circuitry for fear centered on the amygdala. Most

recently, Poulton and Menzies (2002) proposed a nonassociative theory of fear acquisition to account for fears to that are not acquired by conditioning. They claimed that members of a species will show fear to a set of biologically and evolutionary-relevant stimuli without requiring any direct or indirect associative learning experiences involving painful unlearned aversive stimuli. They suggested that the addition of a nonassociative pathway to classic conditioning models of fear acquisition contributes to understanding the nonrandom distribution of fears and phobias and helps account for failures to recall direct traumatic or conditioning events responsible for fear onset among phobic individuals.

Treatment

The most common treatment for phobias is exposure therapy. While this treatment can be delivered using approaches that vary across parameters such as duration, frequency, and context of exposure and degree of therapist involvement, exposure therapy has been shown to be effective across phobic disorders (Barlow 2002). The most common exposure approach is in vivo exposure. In vivo exposure involves systematic, repeated, and direct contact between individuals and their feared or avoided object or situation. Recent technological advances have introduced a new way to deliver exposure therapy using virtual reality (VR). VR integrates a number of systems including computer graphics, body tracking devices, and sensory input devices to immerse individuals in a real-time computer-generated virtual environment (Powers and Emmelkamp 2008). It can also be used to combine the real world with virtual elements (referred to as augmented reality [AR]). VR allows phobic individuals to confront virtual representations of their phobic stimuli. Advantages of VR over in vivo exposure include the ability to conduct exposure treatment in the therapist's office, the delivery of more tailored, personalized exposure, and potentially increased cost-effectiveness. Crucially, a meta-analysis found VR treatment to be as effective as in vivo exposure (Powers and Emmelkamp 2008), while

another study found individuals chose VR over in vivo exposure (Garcia-Palacios et al. 2007), suggesting using VR may help increase the low rates of individuals who seek treatment for phobias.

Conclusion

Phobias are objects, places, situations, feelings, or animals that invoke intense and crippling feelings of fear and anxiety. Unlike typical fear, phobic fear is always irrational and out of proportion to the danger posed by the stimulus, and thus is not adaptive. Phobic disorders, classified as anxiety disorders, consist of specific phobia, social phobia, and agoraphobia. Theories on the development of phobias suggest humans seem prepared to easily acquire phobias to stimuli with biological and evolutionary relevance, with or without a prepared conditioning experience pairing the stimulus with an aversive event. Exposure therapy is the most effective treatment for phobias, allowing phobic individuals to confront their feared stimuli and can be delivered in vivo or using virtual reality.

Definition

Phonemes are the basic building blocks of speech sounds, which are symbolic in nature.

Introduction

Phonemes are perhaps the most intuitive of the units that constitute the speech sounds of language: They are essentially the consonants and

vowels that most people are familiar with. Besides being a product of vocalized speech, current phonological theory views phonemes as abstract mental representations of sounds. Linguistic overviews of the phoneme can be found in classic works such as Sapir (1925), Swadesh (1934), Twaddell (1935), Jones (1967), and a comprehensive modern overview is found in Dresher (2011).

Signs and Phonemes

The modern disciplines of semiotics and linguistics have their roots in Saussure's "Course in General Linguistics" (Saussure 1972). This important work introduced the notion of the linguistic *sign*. This idea has given rise to two important concepts that will be explored here: *symbols* and *phonemes*. These concepts have proven important for the way that researchers think about language today: as a system of symbolic representation, including in the domain of the sound system of a language.

Saussure envisioned language as a set of signs – a meaning coupled with a sound pattern. The representation of a sign, according to Saussure, would be the following, where the image of the cat is intended to represent its semantics and where the symbols (from the International Phonetic Alphabet, used for the phonetic values of sounds throughout this entry) are intended to represent the actual pronunciation of the word “cat” (Fig. 1).

For reference, Saussure terms the concept of the cat the *signification*, the sound pattern used to express the concept the *signal*, and the pairing of the two a sign. That this sign is an arbitrary pairing of sound and meaning is evidenced by the fact that other languages have different words for the same meaning (i.e., the concept “cat”): *chat* in French, *gato* in Spanish, and *duus* in Gitksan (an indigenous language of British Columbia, Canada), all of which have a different way of pronouncing the word. In this way, there is nothing inherent in the concept of “cat” that motivates the sound structure used for the word. The way humans use language involves arbitrary symbolic representation. Thus, while most of semiotics

Phonemes and Symbols, Fig. 1 Sign of “cat”

have focused on semantics and meaning, there is also the phonological aspects to be concerned with, which will be focused on here.

This discussion of semiotics also dovetails with the other remarkable fact about signs: that they constitute systems of contrast. The word “cat” is distinguishable from similar words such as “bat” “mat” “sat” “fat,” etc., by the fact that each of the initial sounds is contrastive: changing the initial sound triggers a difference in meaning. This characteristic of contrast is a hallmark of phonemes. Another fact worth mentioning is that speech is produced as a continuous acoustic stream of sounds; there are no breaks or pauses that naturally fall between speech sounds in a word. Despite this, humans are able to segment this continuous stream into categorical, isolable units. These units are symbolic in the sense that they are discrete and represent the content that is the basis for contrast. These symbols are abstract representations in the mind. There are also operations, as a part of grammar, that are able to operate on and manipulate these symbols, and this is what is considered a phonological grammar.

The abstract, symbolic nature of speech sounds is what leads to the core concept of the phoneme, a term first used in its current sense by Baudouin de Courtenay, who defined the phoneme as “the psychological equivalent of a speech sound” (1972,

p. 152). Phonemes provide a unified, abstract basis for speech sounds that appear in different contexts. Structural linguists such as Trubetzkoy (1969) and Sapir (1925) were among the first to consider the phoneme a psychological concept, i.e., a mental structure or representation, and it was Jakobson (1962) and Trubetzkoy (1969) who first discussed the phoneme in terms of its “contrasting properties.”

The idea of phonemes representing a unified sound among multiple sounds can be explored here further. Phonemes can be realized differently in different environments or distributions. Take for example the vowels of Mokilese, an Oceanic language spoken in Micronesia (data from Harrison 1976, p. 26). Mokilese has a set of voiced vowels, i.e., those which are produced with the vocal folds vibrating, as the vowels of English are produced. This set includes the vowels [i, u, e, o, ε, ɔ, a]. In addition to the voiced vowels, the language also makes use of voiceless versions of [i] and [u], which will be notated as [i̥] and [u̥]. Voiceless vowels are a typologically rare phenomenon (cf. Maddieson 1984), and in Mokilese, they have a very restricted distribution, occurring only between other voiceless consonants. For example, the vowels in *mine* “to be in a place” and *lujuk* “to tackle” are not devoiced; but between voiceless consonants, there are voiceless vowels, such as in the words *kisa* “we two” and *supwo* “pile of firewood.” It is likely that the environment between two voiceless consonants helps to facilitate the devoicing of the vowel. At some level of analysis, then, it becomes useful to think of the voiceless vowels and their voiced counterparts as being the same basic sound; the two variants just happen to surface in slightly different phonetic ways, depending on the environment in which each is found.

Phonemes and Allophones

A principal concept in phonology is the distinction between phonemes and *allophones*. Phonemes are sounds that are contrastive in a language, in the sense outlined above. For example, the two words “teen” and “keen” differ with

respect to one sound: the initial consonant [t] versus [k], respectively. These are the only sounds that are different when comparing these words, and they make these words contrast with each other, evidenced by their having different meanings. One way to conceptualize this is to say that phonemes are not predictable; in other words, there is no way of predicting ahead of time whether a word will have a word-initial [t] or [k] in English. As a principle, all unpredictable information for a given word must be packaged into the mental lexicon in the entry for that word. This idea will be relevant when different levels of representation are introduced.

While phonemes are the unified mental representations of sounds, *allophones* are the different surface variants, or expressions, of these phonemes. In the Mokilese case above, the voiced [i] and voiceless [i̥] would be allophones – surface variants of a single phoneme /i/ (where phonemic forms are placed between slashes, and allophones are placed in brackets). The same is true of [u] and [u̥]. Allophones are not contrastive in a given language. Instead, they are merely two different instantiations of a single phoneme in different contexts. Allophones are simply distributional variants. In Mokilese, the voiceless allophones of the vowels show up in contexts between voiceless consonants, whereas the voiced allophones are found in all other contexts. The distribution for these vowels in Mokilese is *complementary* in the sense that the distribution for each vowel type does not overlap with the other.

The contrasts that are available in a system differ across different languages. The net result is that languages have different phonemic inventories. Thus, the phonemes that are employed in different languages provide for a rich parameter of cross-linguistic variation. For example, the sounds /b/ and /m/ can be independently shown to be phonemic in English, as they are contrastive in words like “beat” and “bat” versus “meat” and “mat.” While they are phonemic in English, these consonants are not contrastive in Pirahã, a Muran language of Brazil (data from Sandalo 1989, p. 39). In this language, these consonants do not signal meaning differences. Observe the differential behavior of the word /mege/ when in different

environments (where // indicates a pause and where the relevant word is underlined):

a.	<u>mege</u> kaobée	“to fall on the floor”
b.	kapeega <u>bege</u> kaobée	“the notebook fell on the floor”
c.	kapeega // <u>mege</u> kaobée	“the notebook//fell on the floor”

This single word changes shape in different contexts: in utterance-initial position (a), the word begins with the nasal sound [m]. The same is true for the word when it follows directly after a pause (c). However, when the word is not in initial position, it surfaces as [bege] instead of [mege]. This is a case of an *alternation*. It can be assumed that there is a single underlying consonant sound in the word and that this sound is alternating between [b] and [m] when the word is in different environments. This alternation indicates that [b] and [m] in the language are allophones, because they are in a complementary distribution: [m] occurs utterance-initially, while [b] occurs in all other contexts. Because the sounds are not found in the same environments, they cannot possibly be used to distinguish different words or serve to trigger a contrast. Thus, the allophones of this b/m phoneme are predictable in the sense that given a particular environment, it is predictable which of the two sounds will surface:

Pirahã:	moopai “throat, neck”	(<u>m</u> only found word-initially)
	xísoobái “down”	(<u>b</u> only found word-medially)

In very much the same way, the voiceless alveolar stop [t] and the voiceless aspirated stop [tʰ] (which involves a short puff of air after the release of the consonant) are not contrastive in English: [tʰ] is found word-initially in words like “tea” and [t] occurs after the consonant [s] in words like “steep.” These two sounds do not have overlapping distributions, and therefore it is not possible to have *contrasts* between [tʰ] and [t] in English.

Minimal Pairs

The principle that allophones occur in complementary distribution leads to an empirical test for

phoneme-hood: the use of *minimal pairs*. True minimal pairs are pairs of words that differ only in a single sound. This difference determines that the sounds are contrastive (as nothing else in the word could trigger the difference, hence the descriptor *minimal*). The following constitutes a set of minimal pairs in English, where the only sound that is different in each case is the one in word-initial position (where all of these rhyme for West Coast American English speakers, and where some vowels will be subject to dialect variation): “hot,” “pot,” “tot,” “cot,” “lot,” “rot,” “yacht,” “watt,” “bought,” “got,” “not,” etc. The minimal pair test is not always possible, as many languages will conspire against having minimal pairs of sounds in particular contexts. In some cases, near-minimal pairs suffice as a test, so long as all environments can be controlled for (and demonstrably do not induce allophony). There are also possible gaps, such as “mot,” which is not a word for most English speakers, raising the question of whether /m/ is a phoneme of English. This is in fact a phoneme of English, as there are plenty of other contrasting pairs that can be observed, including “meat” versus “beat” versus “peat,” or “man” versus “ban” versus “pan.” Thus, it can be established that the sounds m/b/p all contrast in English, and since it was established above that h/p/t/k/l, etc. are all phonemes (by virtue of participating in other minimal pairs), then /m/ can be added to the list. The nonce word “mot” just happens to be an accidental gap of English, which is reinforced by the fact that “mot” is perceived to be a *possible* word in the language; one that could, for instance, be used for a new concept, product, or piece of technology.

Phonemic Inventories

Across languages, then, there are gross differences in the phonemes that exist. These phonemes that are used constitute the phonological *inventory* of a language. For instance, the inventory of consonantal phonemes in English (depending on the dialect) includes: /p, t, k, b, d, g, f, v, θ, ð, s, ʃ, ʒ, h, ʈ, ɖ, m, n, ŋ, l, ɹ, j, w/. In comparison, the inventory of consonantal phonemes of Urama, a language of Papua New Guinea (data from Brown et al. 2016),

includes only /p, b, t, d, k, g, v, h, m, n, r, w, j, ʔ/. On the face of it, Urama has fewer consonantal phonemes than English. There are, however, qualitative differences in that the Urama phonemic inventory has the consonant /ʔ/, which is a glottal stop (produced with a complete closure of the vocal folds), which English lacks in its phonemic inventory. Likewise, languages can differ in their vowel inventories. Some varieties of English have the vowels /i, ɪ, u, ʊ, e, ε, o, ɔ, æ, ɑ, ə/, while Urama has only /i, u, e, o, a/- a proper subset of the vowels of English. These differences yield a very simple and intuitive metric for comparing the sound systems of languages; an overview of the phonemic inventories of several hundred languages of the world is provided by Maddieson (1984).

In addition to the raw inventories of sounds in languages, there are combinatorial differences across languages. While two languages may have roughly the same phonemic inventories, the restrictions on how those phonemes can be combined into sequences can be different. Nasioi, a Papuan language of Bougainville, has a consonantal phonemic inventory that is very similar to Urama and a vowel inventory that is nearly identical. While vowels are freely sequenced in words in both languages, there are fairly tight restrictions on the sequencing of consonants. In Urama there is an absolute prohibition on consonant clusters, whereas in Nasioi a very small number of consonant cluster types are allowed. The sequencing of phonemes and the restrictions in languages are what is termed *phonotactics*. Data of this sort from over 1,000 languages is available in the World Phonotactics Database (Donohue et al. 2013).

Levels of Representation

While the nature of phonemes and allophones has been defined, what remains to be explained is the details of the *relationship* between phonemes and allophones. It might help to think of this in terms of different *levels*. One thing that was established early on is that the unpredictable, phonemic contrasts in languages must be encoded in the lexical entry for any given word. This lexical structure is what is termed the *underlying representation* of a

word. This is the level at which phonemic information is present, including which consonants and vowels make up the word and in which order they are sequenced (i.e., the information for “tip” must not only specify the consonants and vowels that are present but also the fact that they are ordered /t-i-p/, and not /p-i-t/, like the word “pit”). Since phonemes are not predictable, and not derivable by any principle, then this information must be stored for each word. In contrast, the surface or phonetic form is the level where all of the phonetic detail gets “implemented” by the articulators in the vocal tract, such as the tongue, lips, vocal folds, etc. The underlying form is an abstract representation – it is categorical and symbolic in nature. The surface form, on the other hand, is gradient and subject to the constraints that the vocal tract imposes on it.

Turning back to the Mokilese example, there are two things that can be noted about the vowel allophones. One is that cross-linguistically, voiceless vowels are extremely rare. The other is that the voiceless vowels are found in a very limited environment, i.e., only between two voiceless consonants. The voiced vowels, on the other hand, appear to be the forms occurring in the most widespread environments (i.e., everywhere *except* between voiceless consonants; this is termed the *elsewhere* case). This provides good reason, then, for the voiced vowels to be in the underlying representations of words in Mokilese, and the voiceless vowels are the forms that are derived on the surface. Since the underlying forms are inferred on the basis of this information and the surface forms can be observed in uttered words, the challenge is to get the phonological grammar to map the underlying forms to the surface forms. Another way of putting this is that the grammar must convert the voiced vowels of Mokilese to their voiceless counterparts only in contexts where they are between voiceless consonants. This process is termed a *derivation*.

Symbolic Operations and Rules

In order to *generate* a set of allophones from an underlying phoneme, there must be some sort of operation that maps the underlying form to the

surface form, i.e., an operation which is responsible for deriving the set of allophones for any given phoneme. This mapping can be formalized as a rewrite rule (see Chomsky and Halle 1968). A rewrite rule takes a string of symbols as input and returns a string of symbols as output. The process involves changing one (or more) of those symbols when it is in a specific environment. Taking the example of Mokilese vowels, a rewrite rule might take all instances of the set of phonemes {i, u} and change these symbols into {i̥, u̥} when the symbols are located between two voiceless consonants. Formalizing this statement would look something like: /i, u/ → [i̥, u̥]/C₁__C₂. Given that phonemes are abstract, symbolic mental units, they can be subject to rules of this type.

The resulting derivation from underlying to surface representation can be schematized as such:

Underlying Representation (Lexical Structure)

Application of Rules

↓↓↓↓

Surface Representation (Phonetic Structure)

Distinctive Features

While phonemes are considered to be the atomic structures of phonology, they also have a rich internal structure. Because they are symbolic in nature and because they participate in contrasts in languages, phonemes have the appearance of basic, atomic units. They are, however, reducible to smaller, dependent units. As established above, phonemic distinctions can be characterized by oppositions. Each of the dimensions that can create these oppositions can then be expressed as a set of distinctive features (see Jakobson et al. 1952 and Chomsky and Halle 1968, which are classic works on early approaches to distinctive features). For instance, the contrast between “bat” and “mat” is only along one dimension: the soft palate is raised in the first sound of “bat,” keeping all of the airflow moving through the oral cavity, while

in “mat” the first sound involves a lowered soft palate, allowing airflow to move through the nasal cavity. Thus, the difference between /b/ and /m/ can be characterized as a difference in the feature [nasal], which can be characterized as an abstract motor command for the soft palate. Thus, /b/ is [−nasal] and /m/ is [+nasal]. Each possible contrast then constitutes a distinctive feature, which also presumably captures a natural class of speech sounds in languages. Each phoneme, in turn, consists of a bundle of values for each distinctive feature.

Recent theories about distinctive features view many features as being semi-independent of the phoneme, rather than an intrinsic component of it. This general approach is termed *nonlinear phonology* and assumes that phonological representation is not simply a linear string of phonemes such as consonants or vowels, each with their own bundle of distinctive features, but rather a loosely organized sequence of speech sounds, where distinctive features can potentially be shared across different sounds. This is the insight of Goldsmith (1976), who showed that in many languages where tone is contrastive, tones can exhibit behaviors that suggest they are somewhat independent of the vowels that they are realized on. A related idea adopts the notion that distinctive features are organized internally within the phoneme into phonetically motivated groupings such as place of articulation, manner of articulation, and voicing. This type of *feature geometric* model (Clements 1985; Sagey 1986) restricts the independence of features within a set of classes. The intuition is that in contexts of assimilation, there is a single gesture or distinctive feature that is being *spread* from one phoneme to another. In English this is illustrated with cases of voicing assimilation which affect the plural marker *-s* (phonologically, /-z/): cat/cat[s], dog/dog[z]. If it is assumed that /-z/ is the underlying representation of the plural marker, then it can be observed that when it follows voiceless consonants, it also becomes voiceless. In this case, since it is a single gesture involving a single articulator (the vocal folds) which is being held across two consonants in sequence, it makes sense to say that both consonants are specified with a single [−voice] distinctive feature. In this way, nonlinear phonology

is a radical departure from the classical view of the phoneme in that it prescribes a semi-autonomous existence for distinctive features and reduces the role of the phoneme in the linearization of speech sounds.

Conclusion

Much of modern phonology has placed a great deal of emphasis on the phonemic level of analysis; however, more contemporary approaches have explored nonlinear models that assume a more limited role for the phoneme. Despite these new developments, the phoneme remains a core area of investigation and is also assumed to be the “core” unit of phonology. In his contemporary in-depth overview of the phoneme, Drescher (2011, p. 241) states that despite the new areas of focus in phonological theory, “This does not mean that the phoneme plays no role in modern phonology; closer inspection reveals that the phoneme is far from dead.”

Definition

The phonological loop is the subsystem of working memory that deals with auditory information. It consists of two parts: a short-term phonological store with auditory memory traces that are subject to rapid decay and an articulatory rehearsal process that can revive the memory traces.

Introduction

The multicomponent model of working memory (Baddeley and Hitch 1974) is considered to be one of the most influential models of working memory. According to this model, several components are involved in the execution of working memory: the central executive, the phonological loop, the visuospatial sketchpad, and a fourth component called episodic buffer (Baddeley 2000). Among these components, the phonological loop is specialized for the retention of verbal information over short periods of time. In addition, the phonological loop is comprised of two components, a phonological store which can hold memory traces for a few seconds before they fade, and an articulatory rehearsal process which helps to maintain decaying representations in the phonological store through subvocal rehearsal. Because of the relative tractability, the phonological loop has received more attention than other components in the model of working memory.

Phonological Loop and Rehearsal

Articulatory loop; Phonological short-term memory; Phonological store and articulatory rehearsal

The Two-Component Model of Phonological Loop

In order to store phonological information for a short period and prevent its decay by continuously refreshing it, it was proposed that there should be two components in the phonological loop, and the two components are to some extent independent. Take memorizing a telephone number for example, the digits of the phone number are immediately entered into the phonological store, where they could be maintained for 1–2 s. And the articulatory rehearsal process helps maintain

the digits in the phonological store by repeating the phone number.

If the information is visually presented, for example, a telephone number printed on a paper, it can be transformed into phonological information by subvocal rehearsal and then be encoded into the phonological store. Therefore, the articulatory rehearsal process has two functions: to maintain the memory traces in the phonological store and to transform visual information into articulatory information.

Evidence for the Phonological Loop

A number of efforts have been paid to verify the existence of the phonological loop as well as the two components of it since the model was proposed by Baddeley. The followings are the most noticed phenomena found under laboratory manipulations that could support the existence of the phonological loop and could also be seen as the characteristics of it.

- (a) The phonological similarity effect, one of the most robust effects regarding the phonological loop, refers to the phenomenon that people tend to be much less accurate in recalling sequences of similar-sounding words (e.g., man, mad, map, mat) than recalling sequences of words that are phonologically distinct (e.g., day, sup, few, cow). Besides, the similarity of meaning has little effect on recall. The phonological similarity effect indicates that verbal information is mostly coded phonologically, and the phonological store indeed exists (Conrad and Hull 1964).
- (b) The articulatory suppression effect refers to the phenomenon that when participants are required to say something irrelevant aloud while memorizing lists of words, the performance of recall would be impaired, indicating the importance of articulatory rehearsal process (Richardson and Baddeley 1975).
- (c) The word-length effect refers to the tendency for participants to have more difficulty in an immediate serial-ordered recall of a sequence of long words (e.g., university, aluminum, hippopotamus, refrigerator) than in that of a sequence of short words (Baddeley et al. 1975).
- (d) The irrelevant sound effects refer to the research findings that immediate recall is impaired by the irrelevant spoken material presented at the same time or subsequently (Jones and Macken 1993). Notably, when the target materials are presented visually, the effect of irrelevant sound would be removed by articulatory suppression, but if the target materials are presented auditorily, the irrelevant sound could still reduce the recall performance under articulatory suppression (Hanley and Broadbent 1987).
- (e) Transfer of information between codes refers to the process where visual information is transformed into phonological codes by subvocal rehearsal, and such a process could be blocked by articulatory suppression (Murray 1968).

Besides the phenomenon mentioned above, neuropsychological and neurobiological findings also support the structure of the phonological loop. For example, with a deficiency of the articulatory rehearsal process, aphasic patients with dyspraxia are unable to set up the speech motor codes necessary for articulation (Waters et al. 1992). The phonological store has been found to be associated with left supramarginal gyrus, while articulatory rehearsal is associated with Broca's area, according to the evidence from fMRI and PET studies (Awh et al. 1996; Paulesu et al. 1993).

Evolutionary Functions of the Phonological Loop

Besides as a subsystem of working memory, the evolutionary role of the phonological loop (i.e., the reason why the phonological loop has evolved in human being) has also attracted much attention. Studies are mainly focused on the role of the phonological loop in advanced psychological processing such as reasoning

and reading comprehension. For example, research found that the phonological loop plays a role in syllogistic reasoning (Gilhooly et al. 1993) and analytic reasoning (Prabhakaran et al. 1997).

Evidence also shows that the phonological loop assists the process of reading comprehension. The articulatory suppression, which would disrupt the functioning of the phonological loop, was found to increase the accuracy of error-judgments of unacceptable sentences (Coltheart et al. 1990).

A more important function of the phonological loop, as proposed by Baddeley, is to facilitate the acquisition of language. The capacity of learning native vocabulary in children is assumed to depend on the phonological loop. Moreover, the ability to learn a second language of both children and adults could be directly predicted by the phonological loop (reviewed by Baddeley et al. 1998). Based on empirical studies, it is suggested that the phonological loop should facilitate language acquisition in two ways: the phonological store should provide relatively unconstrained temporary representation for new phoneme sequences, and the articulatory rehearsal process should facilitate learning.

Conclusion

The topic of phonological loop has proved to be more robust and productive than other components of Baddeley's model of working memory. The simple model of the phonological loop consists of two components, the phonological store and the articulatory rehearsal process. Series studies have explored the cognitive patterns that can prove the existence of the phonological loop and its components, such as the phonological similarity effect and the articulatory suppression effect, along with the neuropsychological evidence. Importantly, advanced psychological processing such as reasoning, reading comprehension, and language acquisition have been found related to the functioning of phonological loop.

Definition

A class of statistical methods that incorporate information about phylogeny in order to test evolutionary hypotheses.

Introduction

Phylogenetic comparative methods are an array of statistical procedures developed to analyze evolutionary models including the reconstruction of ancestral traits; the coevolution of morphological, physiological, behavioral, and cognitive features; the effects of socioecological factors upon these characteristics; and the degree of evolutionary diversification and extinction, among others (Nunn 2011). The pertinence of their use is due to the fact that closely related species are expected to resemble more to each other than more distant taxa. This poses serious pseudo-replication issues at the time of conducting statistical analyses. However, phylogenetic comparative methods not only reduce the likelihood type I, but by meeting the required statistical assumptions, they also increase power and decrease type II errors (Macleán and Nunn 2017). This entry will briefly discuss some of the main diagnostic analytics used to determine the presence of phylogenetic dependencies, as well as some of phylogenetic methods currently employed in comparative psychology including phylogenetic independent contrasts, phylogenetic generalized least squares regression, phylogenetic logistic regression, phylogenetic generalized mixed model, phylogenetic path analysis, and phylogenetic meta-analysis. This review is an introduction to these approaches.

Phylogenetic Signal

This concept refers to the degree of phylogenetic dependence of a trait across species (Freckleton

et al. 2002), where phylogenetically close taxa are expected to be more similar to each other, relative to other species sampled at random from the tree (Nunn 2011). Over the years, various diagnostics destined to detect trait preservation had been proposed. Pagel (1999), for example, developed two scaling parameters to detect signatures of trait evolution in continuous data. The first parameter, δ (delta), was developed to distinguish the occurrence of fast and early trait evolution, followed by a period of stabilizations (as is observed in instances where δ is lower than one). Alternatively, instances when δ is equal or larger than one are associated with trait evolution occurring closer to the tips of the tree relative to more ancestral nodes (Nunn 2011).

Pagel also proposed λ (lambda) to determine if the evolutionary patterns in the phylogeny fit the degree of resemblance across species in the data (Pagel 1999). This approach rescales the tree structure as represented by variance-covariance matrix (Nunn 2011). According to Nunn (2011) when λ is close to one, the diagonal representing the variance will indicate if the model is equivalent to a model following Brownian motion evolution (the variation of traits occurs as a random walk in proportion to the passage of time represented by the length of the branches in the tree; Felsenstein 1985). Alternatively, if λ is zero, the covariance observed in the off-diagonal should also be zero, as well as the length of the branches (Nunn 2011). Consequently, λ values lower than one indicate that the trait of interest is less similar across species that it would be predicted based on the phylogeny, and a Brownian motion model of trait evolution (Pagel 1999). It is worth noting, however, likelihood ratio tests are required to determine whether λ is statistically significantly different from either one or zero (Freckleton et al. 2002; Nunn 2011). The precision of this diagnostic is dependent on sample size. Simulations indicate samples with fewer than 30 species compute equivocal λ values (Freckleton et al. 2002).

Another more recent metric K is also used to determine the level of phylogenetic signal in continuous traits (Blomberg et al. 2003). This procedure was based on the observed mean squared

error (MSE) and its corresponding expected value assuming the occurrence of Brownian motion, considering the structure and size of tree (Blomberg et al. 2003; Nunn 2011). One of the advantages of K is that in addition to examining the phylogenetic signal of a single trait, it can also be applied in analyses with multiple traits across more than one phylogenetic tree. This allows the analysis of trait change patterns across various evolutionary models (Blomberg et al. 2003). Similar to Pagel's λ (1999), K values lower than one indicate that the data and the tree structure do not suit a Brownian motion model (Nunn 2011). Some causes associated with a low K include the presence of homoplasies, where traits shared across species evolved in the absence of a common ancestors, or due to a high incidence of measurement error, either at the level of tips, at the length of the branches, or in the topology of the tree (Blomberg et al. 2003). Instances where K is greater than one indicate close species resemble each other, and trait evolution followed Brownian motion (Nunn 2011). Blomberg et al. (2003) observed the power to accurately estimate the phylogenetic signal, relied as well on the sample size. According to their simulations, samples with more than 20 species achieve adequate power levels (more than 0.8).

Abouheif (1999) also suggested adapting a test for serial independence (TSFI), developed by von Neumann et al. (1941) to determine the presence of nonrandom patterns in a series to a phylogenetic setting. This test examines whether the observations in the dataset followed an ordered sequence on the tips of the trees (Abouheif 1999). A positive autocorrelation is associated with similarity due to common descent, whereas negative values are product of convergent evolution (Abouheif 1999). TSFI allows the analysis of phylogenetic signal in binary discrete traits (Nunn 2011). Even though TSFI does not require any information on the length of the branches or the tree topology, it is a parametric test assuming the data is normally distributed. Other methods used to conclude the presence of phylogenetic signal in discrete traits are based on model comparison considering a null model with the characters reshuffled on a series of trees (Maddison and

Slatkin 1991). The series of randomized simulations create the distribution of s , the minimum number of transition from one state to the other and its reverse (Maddison and Slatkin 1991). Another approach, Moran's I (1950), relies on the computation of spatial autocorrelations to estimate phylogenetic dependencies. This diagnostic is estimated assuming a multidimensional matrix; however, as mentioned by Abouheif (1999), this procedure requires a previous knowledge of the branch lengths and the location and number of changes occurring in the phylogenetic tree.

Phylogenetic Independent Contrasts

Although alternative analyses for continuous variables had gained popularity in the last decade (see below), the use of phylogenetic independent contrasts (PIC) remains widespread. Felsenstein (1985) proposed this method as an alternative to nested analyses of variance, with the former considering genera or families rather than species as the unit of examination. PIC are calculated as the difference between the values of a trait in two closely related species, after taking into consideration the length of the branches in the phylogenetic tree (Swenson 2014). These computations are recursive, starting at the tip of the tree and progressing down to the root (Nunn 2011). However, branches are only used once in these computations (Felsenstein 1985; Nunn 2011). Consequently, the quantities used for the estimation of a contrast between two species, such as A and B, are excluded from further analyses. To circumvent this restriction, a subsequent step calculates the following contrast between the next phylogenetically close species, such as C, and the common ancestor of the previously used taxa (A and B). The value of the ancestral node is not the average of the daughter species, but rather it is extracted by weighing these quantities by the length of the branches (Nunn 2011).

Even though PIC is often used as an avenue to explore trait coevolution, this method calculates separately the contrasts for each trait, and in later stages, the researcher must compute a correlation or regression analysis to test hypothesized

associations between traits (Swenson 2014). It is relevant to mention that even though independent contrasts are frequently employed in bivariate correlations or other general linear model procedures, an advantage of this method is that it provides researchers with the flexibility of exporting contrasts and conducting more sophisticated analyses with them (e.g., factor analysis, principal components analysis, multilevel modeling, structural equation modeling). This method, however, relies on certain statistical assumptions. For example, outliers should be removed, residuals should indicate homogeneity of variance, and the variance observed should fit a Brownian motion model. Standardization is often used as a tool to solve heteroscedasticity issues. This approach divides the contrast, by the square root of the sum of branch lengths, allowing each value to display similar levels of expected variation (Nunn 2011).

Another recommendation at the time of running PIC analysis is forcing the regression line to go through the origin (Swenson 2014). This practice is due to the fact that the sign of the subtraction, positive or negative, is arbitrary (Nunn 2011). By forcing the intercept to zero, the regression line can go through the mean of X and Y (Nunn 2011). As mentioned by Nunn (2011), one of the advantages of this practice is that it allows the model to regain one degree of freedom. Although it may seem as an inconsequential difference, it is often the case sample sizes in this type of analysis that are considerably smaller, affecting the power of the test.

Phylogenetic Generalized Least Squares Regression

Although a variety of traits evolved under Brownian motion, an array of characteristics do not follow this evolutionary pattern. Consequently, analysis relying on PIC may not be adequate. Phylogenetic generalized least square regression (PGLS) is another method used to determine the association or prediction between two or more traits (Symonds and Blomberg 2014). Different from PIC, this approach is often

considered as more general and flexible. (Swenson 2014). For example, PGLS allows the implementation of the observed phylogenetic signal into the model (Nunn 2011; Symonds and Blomberg 2014). Therefore, if no significant phylogenetic dependency is observed across species, the output of the analysis is expected to be equivalent to a non-phylogenetic ordinary least squares regression (OLS; Symonds and Blomberg 2014). Alternatively, if the value of the signal is close to one (e.g., when using λ), the results of the bivariate analysis should be concordant to those of PIC (Nunn 2011). Hence, PGLS may be considered an extension of PIC (Blomberg et al. 2012). It is worth noting, however, the observed phylogenetic signal of the trait is not a statistical issue per se but rather whether the model's residuals exhibit phylogenetic covariance violating traditional statistical assumptions (Maclean and Nunn 2017).

Another advantage of this method is that it allows the implementation of models examining ordinal variables and dichotomous categorical predictors (Grafen 1989; Paradis 2006; Symonds and Blomberg 2014). Furthermore, as in ordinary least squares regression, PGLS enables the inclusion of multistate traits coded into binary predictive variables (e.g., dummy coding; Symonds and Blomberg 2014). The estimates of a PGLS analysis are unstandardized b coefficients with its corresponding p -value based on t -test statistic (Paradis 2006). Unfortunately, most phylogenetic packages do not provide standardized estimates. This issue, however, may be solved by standardizing the variables before conducting the phylogenetically informed examination. Therefore, the model's equation is similar to that of an OLS, $y = a + bx + e$. Due to its flexibility, PGLS tolerates the implementation of various evolutionary models for its subsequent comparison (Paradis 2006). Model fit indicators include the Akaike information criterion (AIC), the Bayesian information criterion (BIC), and the negative log likelihood (one employed in likelihood ratio tests).

Phylogenetic Path Analysis

Although exporting independent contrasts and using them in more sophisticated analyses have

been used as alternative approaches to test complex evolutionary models, more recent perspectives circumvent this additional step. The d -separation method (Gonzalez-Voyer and Von Hardenberg 2014), for example, is a tool that not only allows the computation of phylogenetic path analysis but it enables the examination of multiple competing models according to goodness of fit statistics. This procedure relies on the graphical representation of the variables, through a direct acyclic graph (DAG; Gonzalez-Voyer and Von Hardenberg 2014; Shipley 2000, 2013), where squares, also known as vertices, represent the variables in the model, and arrows, or edges, represent the paths between the vertices. Although this analysis shares some features with SEM or traditional path analysis (e.g., edges are not allowed to return to the previous variable but rather continue to next vertex), some significant differences exist between these methods. Whereas SEM directly estimates the path coefficients, the d -separation approach is based on the specification of a list of statements in which each one of these is comprised of a pair of variables statistically independent of each other (Gonzalez-Voyer and Von Hardenberg 2014).

To compute a phylogenetic path analysis, a minimum set of statements is required. This procedure relies on listing all pairs of non-connected variables and cataloguing all "parent" variables with a path oriented toward any of the non-connected pairs (Gonzalez-Voyer and Von Hardenberg 2014). The combination of these two lists is the basic set of statements corresponding to the conditional independencies in the model. To test these independencies, the statements are transformed into linear models such as multiple regressions. However, to account for the effects of phylogenetic closeness, these computations are often conducted through PGLS, with the parent variable and one of the independent pairs as predictors and the second component of the independent pair as a criterion. After estimating the significance tests, a Fisher's C is computed (see Shipley 2016; or Gonzalez-Voyer and Von Hardenberg 2014, for the corresponding formula). This C statistic is contrasted with a χ^2 distribution. The critical value corresponds to the degrees of freedom of

the model which are twice the number of parameters in the analysis (Gonzalez-Voyer and Von Hardenberg 2014). To be considered an adequate model, the significance of the C test is expected to be above the preselected alpha value.

For model comparison, the difference between C statistics is computed with a χ^2 distribution following the difference between the degrees of freedom of the first model minus the degrees of freedom of the second model (Shipley 2013). However, as pointed out by Gonzalez-Voyer and Von Hardenberg (2014), this procedure is restricted to nested models. For non-nested comparisons, the corrected C statistic information criterion (this statistic corrects for small sample sizes), a statistical analogue to the AIC, is required. After estimating the CICc for each model, a Δ CICc can be computed by subtracting the lowest CICc from the model of interest. Instances in which the Δ CICc is less than 3 are often considered to display adequate support (Gonzalez-Voyer and Von Hardenberg 2014; Shipley 2013). In addition to these metrics, it is recommendable to compute CICc weights to determine the probability of each model. Akin to model comparison in traditional statistics (AIC, BIC), goodness of fit indicators provides a guideline, but ultimately the researcher must decide which model exhibits adequate theoretical and statistical parsimony (Navarro 2013). Since multiple models may present similar CICc values and weights, model uncertainty is an issue. Alternative procedures, such as model averaging, which consists on averaging the standardized path estimates, had been found to solve these statistical difficulties (von Hardenberg and Gonzalez-Voyer 2013).

Phylogenetic Logistic Regression and Phylogenetic Generalized Linear Mixed Models

Inspired by the logic behind traditional logistic analysis, phylogenetic logistic regression (PLR) may be used when estimating the effects of a continuous predictor, or dummy-coded variable, for categorical factors with multiple levels, upon a dichotomous criterion (Ives and Garland 2010).

However, due to non-normality issues, these computations rely on the use of a logit function for the probability distribution (Ives and Garland 2014). The model's estimates are non-standardized coefficients, which may be transformed into β by previously standardizing the variables before the analysis. Different from traditional logistic regression, PLR takes into consideration the probability of a trait to change states (e.g., zero to one or one to zero). The switching rate is an indicator of phylogenetic signal (Ives and Garland 2014). Therefore, a low likelihood of change is associated with phylogenetically close species retaining the ancestral character (Ives and Garland 2014). In conjunction with other phylogenetic analysis (see Pagel's method for binary traits; 1994), this approach also takes into consideration the length of the branches between nodes in the phylogenetic tree, with a higher likelihood of change found in longer branches (Ives and Garland 2014). PLR estimates the effects of the predictors after accounting for the changes in the binary criterion.

Other methods destined to the analysis of binary criteria include phylogenetic generalized linear mixed models (PGLMM). This approach not only allows the implementation of statistical functions for nonlinear data, but it also enables the use of phylogenetically informed random variables (Ives and Garland 2010), as well as estimating the parameters through penalized quasi-likelihoods and restricted maximum likelihood (Ives and Garland 2014). According to Ives and Garland (Ives and Garland 2014), the proportion of σ^2 (estimated from the covariance matrix C) is not only an indicator of phylogenetic signal, but it also offers information regarding the underlying equality between PGLMM and PLR. For the authors, instances for a single predictor where $\sigma^2 = 0$ are equivalent to a logistic regression. Alternatively, when σ^2 is greater than zero, it indicates the presence of covariance parameter estimates in the random variable associated with covariances in the states of the criterion (Ives and Garland 2014). Since PGLMM are based on σ^2 values, which measures the level of phylogenetic signal, low σ^2 confounds the computation of accurate estimates.

Correlated Evolution with Categorical Traits

In 1994, Pagel proposed a method based on maximum likelihood estimations. The procedure compared a null model in which two traits evolved independently from each other, and an alternative model build on the assumption that both traits coevolved (Nunn 2011). The best model is determined after contrasting the likelihoods obtained for each model. If the dependent model presents a higher value, then the null hypothesis is rejected. Since the number of parameters ($k = 4$) of the independent model is nested within the dependent model ($k = 8$), a likelihood ratio test is often used to determine any statistically significant difference between the models. These computations, however, assume that the evolutionary modifications are independent on different branches, the change rate remains constant, and these alterations occur in small periods of time (Nunn 2011). Similarly, both traits are assumed to have two levels, or dichotomies, such as the presence or absence of the traits. The values for the independent model are calculated according to a transition matrix examining a trait changing from one of its two possible states (e.g., zero) to a different one (e.g., one). Based on these transition rates, a likelihood statistic is estimated for the states corresponding to each trait and summed over repeated reconstructions (Nunn 2011). In tandem, the same procedure is employed for the second trait.

Due to the fact that the dependent model assumes both traits coevolved, the number of parameters in the dependent model is larger relative to the independent model. The transition matrix considers the change from one state to next depending on the state of the second trait. Consequently, a change in trait A from zero to one requires estimating this change when B is zero and when B is one. The likelihood of the dependent model is estimated via a 4 by 4 matrix, with only one trait changing per time. Each transition between pairs (0,0 to 1,0) is contrasted with a similar transition, assuming the occurrence of an alternative state in one of the traits (0,1 to 1,1). The greater the difference and/or the number of

transition pairs differing among each other, the larger the likelihood. An advantage of this procedure is it allows the implementations of restrictions between the transitions, enabling researchers to test various models after considering the evolutionary evidence concerning the evolution of a trait before the other (Nunn 2011). In addition of estimating the correlated evolution of dichotomous traits through maximum likelihood, an extension of this procedure is often computed using a Bayesian approach in which the uncertainty of the model or the phylogenetic reconstruction is also taken into consideration (Nunn 2011).

Phylogenetic Meta-Analysis

A more recent method consists in estimating the consistency of the phenomena reported by independent studies examining various species, after accounting for phylogenetic closeness (Adams 2008). Traditionally this type of analysis requires collecting the variance, sample, and effect sizes corresponding to each study. Due to the use of different metrics, effects are standardized prior to the analysis (e.g., fisher's z transformation is one of the procedures used for standardization; Lajeunesse et al. 2013). The presence of study heterogeneity is estimated using a Q test (Lajeunesse 2009). However other analytics such as I^2 had been developed (Higgins et al. 2003). It is also advisable to run fail safe tests to conclude the presence of any publication bias. For example, Rosenthal's (1979) and Rosenberg's (2005) approaches are some of the available analytics.

According to Adams (2008) and Lajeunesse (2009), meta-analysis is amenable to a phylogenetic adaptation since both methods are based on generalized least squares calculations. PMA models compute a covariance matrix (Σ ; Adams 2008), considering the observed heteroscedasticity as well as the phylogenetic associations in the model. Hence, the heteroscedasticity is found on principal diagonal of the matrix, whereas the phylogenetic dependencies are in the off-diagonal (Lajeunesse 2009). After modeling the covariance matrix Σ , a weighted mean

effect size is computed. Confidence intervals (95% CI) can be calculated to determine if the average is different from zero. However, a significance test following a χ^2 distribution is also possible (Lajeunesse 2009). A second matrix (P) is comprised of the correlations among the effect sizes after considering the underlying phylogenetic dependencies. Lajeunesse concluded the strength of these correlations is based on the branch lengths of the phylogenetic tree. Consequently, the matrix structure resembles that observed in PGLS.

Even though, the methods proposed by Adams (2008) and Lajeunesse (2009) share some statistical features; the former takes into consideration whether the variation observed in the model is product of within-study error and bias. Lajeunesse (2009) suggested adapting the Q test to its phylogenetic homologue. PMA also allows the implementation of λ or K values in the model. Therefore, the correlation matrix P , comprised of these altered correlations, will be used in the rest of the meta-analytic procedure (Lajeunesse 2009; Lajeunesse et al. 2013). Model comparison not only between non-phylogenetic and phylogenetic models but also among various evolutionary assumptions is feasible. Moreover, models may not only include fixed but also random effects.

Although, akin to other phylogenetic analyses, likelihood ratio tests can be estimated, some authors recommend using AIC scores as indicators of model fit (Lajeunesse 2009). With respect of effect sizes, PMA usually yields lower estimates compared to traditional meta-analysis (Chamberlain et al. 2012). PMA with fixed effects is considerably sensitive to the degree of the phylogenetic signal as well as to the size of the phylogeny (Chamberlain et al. 2012). With respect to random effects PMA, Chamberlain et al. (2012) discovered that although these models are also dependent on its corresponding phylogenetic signal, phylogeny size was not statistically significant. This result, however, should not encourage researchers to disregard phylogeny size. On the contrary, Chamberlain et al. (2012) are emphatic regarding appropriate sample sizes (more than 20 species) for this type of analysis.

Models to Test and Compare Evolutionary Processes

While highly informative of evolutionary conservatism (as opposed to lability) of traits, measures of phylogenetic signal reflect only the *pattern* of conservatism but not the *process* behind it. It is impossible to determine, only with phylogenetic signal and analyses that rely on it, as the ones described above, *why* a trait exhibits high lability and another high conservatism in the phylogeny of interest. In other words, other indices are necessary to examine the evolutionary process, or processes, behind the evolution of a trait – has it been evolving toward an optimal value? Was there an early burst in evolutionary rates due to niche filling, which subsequently decelerated? Are evolutionary rates accelerating as ecological conditions have made the trait more salient to natural selection in recent evolutionary time? Below we summarize the main models that have been proposed to address these questions, which may be tested through a variety of R phylogenetic packages.

Ornstein-Uhlenbeck (OU): The OU model introduces an additional parameter relative to Brownian motion, for the strength of a constraint force, in other words, a selection pressure toward a certain value for all species in the clade being examined (Hansen 1997). While it is believed that this model describes “stabilizing selection,” that is a fallacious statement, as the pressure may drive species in directional selection toward the optimum or reflect adaptation to a fluctuating optimum that is itself constrained (Ingram et al. 2012). As species values are pushed toward the optimum, their earlier divergence is overwritten, with thus recent evolution under the OU model accounting for most of the total trait variance among species in a clade. Note that it is also possible to estimate whether different clades within a phylogenetic tree exhibit different optima (Butler and King 2004).

Early burst (EB): Like the OU model, EB also introduces a new parameter to the Brownian motion model. It describes how evolutionary rates increase *exponentially* through time (Harmon et al. 2010). When this parameter is 0,

Brownian motion can be assumed, as there is no consistent acceleration or deceleration of evolutionary rates. When negative, it reflects niche filling, suggesting that the clade experienced an early ecological opportunity and rapidly speciated, which was followed by exponential reductions in diversification rates as ecological space saturated (Simpson 1953). As such, branches closer to the tip are longer, indicating a period of considerable stasis.

Acceleration: Akin to the EB model, in a model examining evolutionary rate acceleration (commonly with Pagel's delta; Pagel 1999), rates may have decreased across evolutionary time. However, delta larger than 1 suggests accelerated evolution toward the tree tips and thus species-specific adaptations. This model differs from EB by not assuming *exponential* acceleration or deceleration and thus may serve as a good alternative to test similar hypotheses.

A variety of other, less common models also exist: for instance, a drift model permits examining the possibility that a trait has evolved with a directional component, consistently toward smaller or larger values (FitzJohn 2010); yet another model examines the hypothesis of punctuated evolution, with low values indicating that long tree branches reflect stasis, whereas rapid evolutionary changes were concentrated in short branches (Pagel 1994, 2002).

All these models exhibit one more parameter than the Brownian motion model, in addition to the same two parameters of the latter (although the OU model includes four parameters if the phylogenetic tree used for analysis is not ultra-metric; Hansen 1997). As such, they are modifications of the Brownian motion model, each with a different assumption. They may thus be compared through maximum likelihood tests either across themselves or to a Brownian motion model, with AIC comparisons taking into consideration the different numbers of parameters.

Conclusion

Phylogenetic methods include an array of analytics necessary for conducting comparisons and

reconstructions throughout the evolutionary history of a clade. These statistics provide a powerful control for any underlying effects due to phylogenetic closeness. Although PIC and PGLS are often considered as the main tools of phylogenetic comparative researchers, the last decade had seen a considerable expansion in the sophistication of these methods, including the adaptation of generalized linear mixed models, path analysis, and meta-analysis to its phylogenetic equivalent. It is worth to recall that statistical evidence is required prior to conducting these types of analyses. Furthermore, it is recommended to present the results of both traditional and phylogenetic examinations (Nunn 2011).

Definition

Exhibiting behaviors that have the potential to cause tangible harm to another person.

Introduction

Physical aggression – an act that has the potential to cause tangible harm to another person or thing – has been displayed throughout human existence. Physical aggression can be used to achieve a goal such as securing resources (instrumental aggression) or in response to provocation from a potential threat (reactive aggression). Today’s culture has seen a drastic reduction in physical aggression when compared to human’s

hunter-gatherer ancestors, but the behavior is by no means sparse. Despite declines in violence, a recurrent pattern is the tendency for males to engage in more physical aggression than women.

The common assumption is that males possess a greater propensity toward acts of physical aggression than females do. There is significant data to support this claim; however, some experimental and meta-analytical studies show that the relationship between sex and physical aggression may be more complex. The following entry will review the classic view that males are naturally more physically aggressive than females; however, theoretical perspectives claiming that the discrepancy is less significant than commonly assumed will also be reviewed. The evidence concerning theories of sexually dimorphic expressions of aggression will also be examined from an evolutionary perspective. Finally, this entry will discuss the relationship between sex and aggression in a modern context.

Sex Differences in Physical Aggression

Sex differences in acts of physical aggression are present from as early as the first year of life and continue into maturity. Meta-analytic data of 27 studies sampling children with a mean age of 8 found that males engaged in significantly more physical aggression than females (Card et al. 2008). Debate exists over the initial age of detectable differences in aggression between the sexes. However, a recent longitudinal analysis of more than 2000 infants shows acts of toddler physical aggression (biting, kicking, slapping) are more commonly displayed by male infants than by female infants (Baillargeon et al. 2007). This difference is detectable within the first 17 months, refuting previous estimates that differences did not appear until children were 2–4 years old (Archer 2004). Other findings suggest that aggression in boys is most present in front of other boys (Maccoby and Jacklin 1980). Additionally girls too were found to be more aggressive in front of boys than in front of girls, but boys were less aggressive in the presence of girls (Maccoby and Jacklin 1980).

Sex differences in physical aggression persist into adolescence and adulthood. Males across all ages and multiple nations were more likely to self-report, have others report, or be observed displaying physical aggression according to a meta-analysis of 353 studies comprised of nearly 200,000 participants of various ages (Archer 2004). Additionally, this analysis determined self-reported sex differences were most prevalent between ages 18–30 and observed sex differences were most prominent between ages 12–17. Crime statistics also demonstrate that more physical aggression can be attributed to males than to females. Males are responsible for the overwhelming majority (approximately 85 %) of crimes involving physical assault and the vast majority (97 %) of same-sex homicides (Daly and Wilson 1990).

Despite this evidence, numerous researchers insist differences between physical aggressions are exaggerated and previous research is inconclusive or misguided (Frodi et al. 1977). This perspective claims women are equally likely to be physically aggressive, but the context in which females will display physical aggression varies. Additional explanations for reported differences in physical aggression may stem from the fact that males are more likely to cause harm when physically aggressive compared to women. Women may commit acts of aggression equally; however, the act may not cause severe enough harm to be observed or reported (Richardson 2005). Finally, females may act less physically aggressive as they are more often than not of lesser stature (based on size) to other physically aggressive people (Richardson 2005). The sum of these factors creates a context where reports of physical aggression may not reflect actual instances of aggression among each sex. While sex-based differences in expression of aggression is still a contentious debate, research on lifetime anger levels clearly shows both males and females demonstrate equal levels of anger throughout the lifespan (Archer 2004). The explanation for why the sexes may differ in their propensity to engage in physical aggression varies (Archer 2004). These differences between the sexes in

regards to aggression may be best explained by evolutionary theory.

Explanations of Sex Differences from an Evolutionary Perspective

Previous research has attempted to explain sex differences in aggression to differences in testosterone levels. Higher average testosterone levels in males were directly correlated to higher rates of physical aggression in males than in females. However, while this link between testosterone has been supported in primates (Maccoby and Jacklin 1980) there is limited support for this relationship in humans (Halpern et al. 1993). A more compelling argument, based in sexual selection theory (SST), posits the potential costs of being physically aggressive vary for each sex. For males, the benefits (increased resources, increased mating opportunities) gained through physically aggressive acts are more likely to outweigh the potential costs (serious injury or death) of those same acts. Males' obligatory investment in offspring is quite low, thereby making it possible for males to father hundreds of offspring in their lifetime, being hindered only by their ability to gain mating access to females. Thus, using physical aggression to deter rivals, compete for resources, or gain status can have large, positive, fitness consequences. And the alternative (i.e., not fighting) can lead to an evolutionary dead-end for one's genes. However, females potentially have more to lose from acts of physical aggression (Cross 2010). Females have a large obligatory investment in offspring that is time intensive and energetically costly. This substantially lowers their potential reproductive ceiling, compared to males. Moreover, given that females play a much larger role in parental care throughout a child's life, their absence due to injury or death is much more damaging to the wellbeing of the child than the absence of a male caregiver (Campbell 1999). For these reasons, there are far fewer incentives for females to engage in physical aggression to compete for mating opportunities; their reproductive success is better served by investing heavily in a few, high-quality offspring.

Aggression in a Modern Context

While there is plenty of research concerning physical aggression differences, other theories suggest that it is the physicality of aggression, not the aggression itself, which accounts for the differences between the sexes. One theory for the differences in aggression is that males tend to use direct aggression, such as physical aggression, while females prefer to use indirect or interpersonal aggression, a difference most drastic in adolescence, however adults demonstrate a preference for interpersonal aggression in both sexes (Bjorkqvist et al. 1994). This theory is also supported by evolutionary theory in that females may use indirect aggression because it is less likely to result in retaliatory harm. Moreover, females benefit from not using physical aggression, given the risks described above. This is consistent with the drop in its use for girls before menarche (i.e., when they are physically capable of bearing offspring) as males maintain usage into adolescence.

Conclusion

Regardless of whether females have an equal predisposition to physical aggression as males, evolutionary theory provides a solid theoretical framework in which to explain apparent sex differences in the use of physical aggression. In the context of caregiving, the costs associated with physical aggression greatly outweigh the benefits for females while the opposite is true for males. Modern society contributes to these evolutionary differences in the way anger maybe displayed by different sexes; however, as it stands males appear to demonstrate the majority of physical aggression both past and present.

Definition

The visual cues used to judge mate quality.

Introduction

One of the most fundamental problems facing an individual is mate selection: how do we choose a partner? It is important that we are sensitive to the physical cues that honestly signal that one individual is more desirable (i.e., fitter and with a better reproductive potential) than another and use them to choose the partner which is most likely to enhance our chances of successful reproduction. The wrong choice will obviously have a negative impact on an individual's potential for reproduction, so one might expect very strong selective pressures for the development of mechanisms that accurately detect cues to health and

fertility in potential partners. In this context, attractiveness is based on features that accurately index health and reproductive potential.

Female Attractiveness

For female attractiveness, the two indices most widely researched are overall body fat (usually indexed by the body mass index or BMI) and the ratio of the circumference of the waist to the circumference of the hips (the waist-to-hip ratio, or WHR). BMI (weight scaled for height or $\text{kg}/\text{height in m}^2$) is a measure of total body fat and correlates well with more direct estimates of percentage body fat such as through densitometry or autopsy (e.g., Clarys et al. 2005). By contrast, WHR is an index of fat distribution, with a high WHR indicating a less curvaceous lower body shape with higher adipose deposition in the abdominal cavity as visceral fat and a low WHR indicating a more curvaceous lower body shape with low levels of visceral fat. WHR has been suggested to predict a range of health and fertility outcomes (Koning et al. 2007; Wang et al. 2005; Zaadstra et al. 1993).

As a result, Singh (1993) hypothesized that because WHR potentially provides information about youthfulness, reproductive status, and long-term health risks, WHR should be used in attractiveness judgments. This hypothesis is supported by studies that have asked observers to rate sets of either line-drawn figures of women's bodies (Furnham et al. 1997; Henss 1995; Singh 1993) or digitally manipulated photographic images (Henss 2000; Rozmus-Wrzesinska and Pawlowski 2005; Streeter and McBurney 2003). In these studies WHR is manipulated by altering the width of the waist of the figures, and their results suggest that a WHR of approximately 0.7 is most attractive with higher (i.e., less curvaceous) WHRs being rated less attractive. However, altering the width of the waist not only changes WHR but also apparent BMI. As WHR rises, so does apparent BMI, making it impossible to say whether changes in attractiveness are due to WHR, BMI, or both (Tovée et al. 1999; Tovée and Cornelissen 1999). An

additional problem is that some of the manipulations may produce images outside the natural range of variation and so lack ecological validity (see Bateson et al. 2007).

To counter these criticisms, Singh and Randall (2007) asked observers to rate the attractiveness of pre- and postoperative photographs of women who had plastic surgery to redistribute fat from the abdomen to the hip and buttocks. This operation is suggested to reduce postoperative WHR without significantly changing BMI. Postoperative photographs were judged as more attractive than preoperative photographs, leading Singh and Randall to propose that WHR was a significant predictor of attractiveness independent of any overall body mass change indexed by BMI. However, the view of the women in the photographs was restricted to their lower torso and upper thighs. So it is not surprising that participants made judgments based on the WHR, when the waist and hips were all they could see (Cornelissen et al. 2009). It is quite possible that they might have rated them differently if they had seen the whole body.

A simple solution to the use of manipulated bodies is to use unaltered photographs of the whole bodies of real women (e.g., Smith et al. 2007a; Swami and Tovée 2007; Swami et al. 2006a, 2007). Results from these studies suggest that BMI is the principal determinant of attractiveness judgments (with a BMI of around 20 kg/m^2 being optimally attractive), with WHR playing only a very marginal role. However, these studies have the problem that BMI and WHR are often correlated, as has been demonstrated in large-scale health surveys. For example, the Health Survey for England (Health Survey for England 2003), which includes measurements from 2429 Caucasian women of reproductive age (16–45) ranging in BMI from around 15 to 50, shows a correlation between BMI and WHR of 0.46 (see Fig. 1). This correlation raises the problem of collinearity among explanatory variables in attractiveness studies, making it difficult to discriminate between the effects of BMI and WHR.

One approach to separating BMI from WHR is to model how fat is deposited on the female body

Physical Attractiveness,
Fig. 1 Scatterplot of waist-to-hip ratio (WHR) as a function of BMI from the Health Survey for England 2003 data set based on measurements from 2429 Caucasian women of reproductive age (16–45) ranging in BMI from around 15 to 50

as weight is gained or lost (Cornelissen et al. 2009). Understanding how fat deposition changes body shape allows an analysis which separates out lower body shape change based on changes in overall body fat versus estrogen-mediated change in WHR. This analysis shows that shape change due to overall body fat predicts attractiveness judgments but that shape change linked to estrogen plays no significant role. Another approach is to treat torso shape (i.e., moving from the shoulders to the hips) as a waveform and deconstruct the different components of the shape using principal component analysis (PCA). PC1 is highly correlated with both BMI and attractiveness ratings, but not significantly correlated with WHR. PCs 3 and 4 both correlate significantly with WHR, but neither explains significant variance in attractiveness ratings (Tovée et al. 2002; Smith et al. 2007b).

A final piece of evidence comes from eye-movement studies. The pattern of fixations made when judging body mass is significantly different from those made when judging WHR. When judging body mass, observers focus on the stomach, and deviations from this pattern of fixations reduce the accuracy of body mass judgments (George et al. 2012; Cornelissen et al. 2016). In contrast, when judging WHR

fixations are distributed on either side of the body at the level of the hips (Cornelissen et al. 2009). If these two fixation distributions are compared to the pattern of fixations made when judging attractiveness, it is clear that the fixations made to judge body mass are part of the fixations made to judge attractiveness suggesting a role for body mass in attractiveness judgments. However, the fixations made to judge WHR were not present in the distribution of fixations made when judging attractiveness, suggesting that WHR is not an important cue.

This does not preclude some role for WHR in mate selection, such as differentiating between genders or whether an individual has reached sexual maturity. But in discriminating between potential female partners, it does seem to play a negligible role. In addition to BMI and WHR, there are other features that may play a role in female physical attractiveness. Perhaps the best known of these is the degree of symmetry shown by a body. It is suggested that small deviations in bilateral symmetry (a phenomenon called fluctuating asymmetry (FA)) arise owing to developmental stress (such as from disease or parasites) and that these developmental stresses will have a negative impact on an individual's health and fitness. As when selecting a mate, one wishes to

choose an individual with good health and fertility; it is suggested that if one were sensitive to FA, it could be used as an index of a potential partner's suitability. Previous studies have suggested a weak effect of body FA (excluding the face) with its perceived attractiveness. (Tovee et al. 2000; Brown et al. 2008). This result suggests that although symmetry is a significant factor in determining physical attractiveness, it is a comparatively subtle cue compared with BMI or WHR.

Relative leg length (indexed by the leg-body ratio or LBR) seems to be relatively weak, but significant predictor of female attractiveness. The hormone surge during the first menstrual cycle at the onset of puberty causes the growing points in the long bones of the leg to fuse. The result of this is to halt growth in the legs, although growth in the torso continues until adulthood. Leg growth is very sensitive to diet and health. The increase in height in Western populations in the last century has been primarily driven by increased leg length. This means that relative leg length provides a potential measure of childhood health and nutrition, and relatively shorter legs predict a range of negative health outcomes including a high risk of cardiovascular disease (Gunnell et al. 2004), type II diabetes and insulin resistance (Lawlor et al., 2002), and an increased risk of certain types of cancer (Gunnell et al. 2003). Therefore preferring relatively longer legs should select a healthier partner, and a range of studies have suggested a positive relationship between relative leg length and attractiveness (e.g., Swami et al. 2006b; Frederick et al. 2010).

Male Attractiveness

The primary determinant of male attractiveness seems to be upper body shape (a broad upper body and a narrow waist, the classic V shape). It has been suggested that this V-shaped torso represents a muscular, strong body type that would be an advantage in our ancestral environment and therefore be sexually selected (Frederick et al. 2005; Sell et al. 2008). Body fat is an important predictor of male health and mortality (Prospective studies Collaboration 2009; Emerging Risk Factor Collaboration 2011), and a narrow

waist circumference is also important in long-term health and so should also be associated with a low WHR (Lean et al. 1995; Zhu et al. 2002). However, unlike the female thin ideal body, the ideal male body is comparatively heavy, falling at the boundary of the normal to overweight categories of the BMI scale (Maisey et al. 1999; Crossley et al. 2012). As muscle is approximately 20 % denser than fat, more muscular bodies tend to have a higher BMI. Whereas there is a tendency for women to diet to achieve their ideal body, young men are more likely to be influenced by magazines to build up a bigger, more muscular body (Frederick et al. 2005; Cafri et al. 2005). So although the male ideal body is heavier, the additional weight is muscle rather than fat. As discussed above, BMI is a measure of body weight scaled for height and not a direct measure of percentage body fat. Its use in epidemiological studies is due to its ease of administration. The ideal male body is lean with high muscle definition (which requires a percentage body fat below 9–12 %). The male ideal is both muscular and low in body fat (Crossley et al. 2012) (Fig. 2).

There is also a weaker, but significant relationship between attractiveness judgments and height. For example, women prefer taller men in online dating, in questionnaire studies, and in speed dating (Kurzban and Weeden 2005; Fink et al. 2007; Salska et al. 2008). However, this is not a simple linear relationship. Being substantially taller or shorter than the average is linked to a range of negative health outcomes and to reduced reproductive success (Stulp et al. 2012). Additionally, there is the moderating effect of the female observer's own height. Women seem to prefer men taller than themselves, but not too much taller (Stulp et al. 2013). So the "ideal" height will vary dependent on the observers own height. However, the preference for a taller man may not be universal as there is some evidence that it does not extend across cultures (Sear and Marlowe 2009).

Physical Attractiveness Is Adaptive

Evolutionary psychology assumes that certain physical features honestly signal an individual's health and reproductive potential (Buss 2004;

Physical Attractiveness, Fig. 2 Examples of ideal bodies created by the female participants (**a** and **b**) and the male participants (**c** and **d**) using an interactive 3D computer program. Bodies **a** and **c** are the ideal female bodies set by the female and male participants, respectively, and

bodies **b** and **d** are the ideal male body set by the female and male participants, respectively. This illustrates that both men and women share a preference for a very slim but curvy female body and a muscular but lean, V-shaped male body (Modified from Crossley et al. 2012)

Symons 1980). Certain specific values of these features could signal optimal health and fertility; thus, an individual whose features correspond to these values would be regarded as optimally attractive. For attractiveness to be adaptive, it follows that in environments where the optimal values for these features differ due to differences in environmental pressures, the attractiveness preferences should also be different (Anderson et al. 1992; Ember et al. 2005). Moreover, as observers moved from one environment to another, it would be adaptive for them to alter their attractiveness preferences to those that accurately reflected optimal health and fertility in their new environment (Tovee et al. 2006).

This malleability of preferences may be partially based on an observer's physiological state (Swami and Tovee 2006), but the principal mechanism of recalibration seems to be based not on simple visual diet (i.e., the size and shape of the

bodies in an observer's visual environment), but on visual valency (i.e., the value a culture or society places on a particular body size and shape) (Boothroyd et al. 2012). For example, in the Nicaraguan rainforest, the introduction of TV whose content displays a high value on thinner bodies has led to a downward shift in ideal BMI, although the socioeconomic status of the local people has not changed (Boothroyd et al. 2016). This malleability of preferences in response to changing conditions is essential if the perception of physical attractiveness actually plays an adaptive role in human mate selection.

Conclusion

In Western countries a slim female body is preferred with overall body mass being the principal factor in attractiveness judgements, whereas for

the male body a muscular V-shaped body is preferred. However, the perception of physical attractiveness is a flexible ideal and subject to change based on environmental conditions. This allows attractiveness preferences to adapt to reflect changing conditions and so match mate selection preferences to the optimal body size and shape for health and fitness in a specific environment.

Definition

Physical health is a metabolic and cognitive state that involves the absence of any disease and it is obtained via sports, nutrition, and/or ergogenic aids that enable persons to have a suitable life with maximum functionality. *Sports* is defined as all forms of competitive physical activity, through causal or organized participation in teams, which aims to maintain or improve human physical abilities and skills, usually offering entertainment to participants and cheerfulness to winners (for review see Garcia-Falgueras 2015). *Ergogenic aid* is defined by the American governmental regulation and oversight as any training technique, mechanical device, nutritional ingredient or practice, pharmacological method or psychological technique that can improve exercise performance capacity or enhance training adaptations (Kerksick et al. 2018).

Introduction

Physical health is an individual and subjective dimension of each person, that can be reached by many different ways and they all are responsibility of the grown up person. Thus it implies an active approach. Consequently spectators or audiences of sports who watch a sportive competition but do not participate themselves with any physical activity are not improving their physical health. Competition in sport is a necessary but not

sufficient component to carry on with physical activities, because a systematic personal training and working out is a type of sport or physical activity which also achieves well-being similar as competitive team sports (for review see Garcia-Falgueras 2015).

Physical Activity for Mood, Cardiovascular Health and Body Concept

Cardiovascular exercises practiced regularly, which are aimed at increasing oxygen in the blood and changing the heart rhythm for higher metabolic demands (aerobic exercises), have been proved to improve cognitive functions and to have a positive effect on mental health and psychological well-being. Both individual sports such as fitness, jogging, weight lifting, equestrian, foot-ing, distance running, cycling, swimming, tennis, wrestling, and team-based sports such as soccer, football, rugby, etc. are having good effects over sleeping quality, working memory, long-term verbal memory, perceptual abilities, processing speed, cognitive inhibition, and flexibility (Gayda et al. 2017; Hartescu et al. 2015; Rice et al. 2016). Sedentary behaviors are related to cardiovascular and other diseases (Celis-Morales et al. 2018). Gender and age are variables of importance in order to choose which sport to practice (Eime et al. 2016). There are evidences that physical activity can create a better state for the person, because it is related to lower cholesterol levels, blood pressure, and blood lipids (for review see Ogden 2010). Exercises have been used for the treatment of obesity, weight loss, and weigh maintenance, because physical activity, increase of strength and fitness provide good benefits at reducing sedentary behaviors (Celis-Morales et al. 2018; Ogden 2010). With increase in physical activity and functions of the cardiovascular system, a reduction in cardiovascular diseases is obtained (Zheng et al. 2014) and regular exercise has been associated with a range of public health benefits (Hartescu et al. 2015).

Open air exercise practices had significant good effects on sleep quality for middle-aged

and older people (Hartescu et al. 2015), perhaps because of the sun light exposure. It was proved in a group of older adults that the amount of hours spent outside of the home was associated with better cognitive functions and improved physical and emotional abilities (Petersen et al. 2015). This study was performed during the period of one year and longitudinal data checked confirming that leaving home requires significant cognitive functions and resources: posture, way finding, navigation skills, gait, etc. Moreover, biodiversity and contact with the natural environment (parklands with scattered shrubs and trees) and a number of different species perceived (but no spiders or snakes which might raise phobias), provide many psychological and health benefits (van Heezik and Brymer 2018).

Even in minority groups, such as homeless people, in extreme social isolation conditions of risks and weakness (i.e., alcohol and drugs abuse, violence, sexual abuses, and infectious diseases), sports had a positive effect enabling them in building a new self-identity and starting a new life. After 8 weeks of regular sports and fitness, their well-being and reintegration into society were facilitated and improved (Sofija et al. 2018).

But cognitive and other disorders or even severe injuries do also occur in sports, elite athletes being the higher risk group: head injuries, concussions, limb injuries, including mental ill-health and substance use that can be attributed to the intense mental and physical demands of higher levels of competition (Rice et al. 2016). The vulnerability of physical injuries and risks for health are bigger for athletes involved in sports with a particular lean body-shape demand, such as ballerinas and gymnasts among female athletes. A collaborative team effort is required by different professional staff, such as medicine practitioners, psychiatrists, psychologists, etc., to care for the athletes' mental and physical health and assistance in overcoming barriers and stigmas in order to prevent damages, which are linked to the achievements in their chosen careers (Rice et al. 2016).

The endorphins hypothesis is the most popular explanation as to how a physical mechanism underlies the benefits of sports. In the brain, the

hypothalamus produces endorphins in the form of peptides and the pituitary gland releases them into blood circulation. Later, these endorphins act on their own receptors. It has been demonstrated *in vivo* (MRI) that professional runners release endogenous opioids in the fronto limbic areas of the brain after a sustained and intense physical exercise practice. That release is, in fact, closely correlated with perceived subjective euphoria (for review see Garcia-Falgueras 2015).

Anaerobic sports, such as Tai Chi, Yoga, or Pilates, have been shown to improve physical and mental health outcomes, such as proprioception, balance ability, flexibility, self-esteem, and in general, quality of life and sleep, through a controlled conscious diaphragmatic breathing for achieving body relaxation and a calmness of mind (Garcia-Falgueras 2016; Hartescu et al. 2015; Zheng et al. 2014).

Nutrients and Sports

Healthy eating has been recommended in relative quantities and appropriate consumption of food of different groups. They are: (1) fruit and vegetables; (2) bread, pasta, other cereals, and potatoes; (3) meat, fish, and alternatives; (4) milk and dairy products; and (5) fatty and sugary foods (Ogden 2010). However, there are many different combinations of these ingredients and kitchens in almost all homes have their very own personal and subjective concept of healthy food. There seems to be consensus on the effect of culture, ethnic group, history, and personal traits on diet and food consumption. According to Rozin (1980), “*there is no doubt that the best predictor of the food preferences, habits and attitudes of any particular human would be information about his ethnic group. . . . rather than any biological measure that one might imagine*” (for revision see Ogden 2010).

Several aspects do have a role in eating behavior: the hedonic, cognitive, and homeostatic systems are involved in food intake behavior. In obese people, the hedonic side is predominant (Hopkins et al. 2016; Ogden 2010). In metabolism and the body, satiety signals act as a cascade

(Cholecystokinin- CCK; Glucagon-like-peptide- GLP-1; Peptide YY₃₋₃₆ –PYY; Amylin). These substances are received and perceived in a cross-talk interaction by balancing metabolisms to stop the eating behavior (Hopkins et al. 2016). Obesity can be defined depending on the waist circumference; >88 cm in women and >102 cm in men is the measurement for obesity (Celis-Morales et al. 2018). However, this delicate cascade balance and metabolic and psychological equilibrium might be altered for extreme diets, or long periods of imposed starvation (Polivy 1996).

In recent years, an increased number of studies and publications have been done about supplements and complementary nutrients for athletes and sportive people. Exercise and other vital activities require extra energy and resource consumption; hence, many industries and companies are working on this goal to help sportive and active people. For instance, creatine supplementation intake, one of the most popular nutritional ergogenic aids for athletes, has been proved to have benefits in exercise, sport, and medicine for postexercise recovery, injury prevention, and thermoregulation (Kreider et al. 2017). Creatine is naturally found in meat and seafood, not always available in the right proportion for all those that practice sports. In animal experiments, it was tested and found that 5 days of creatine monohydrate administration might have a neuroprotective effect, ameliorating the extent of cortical damage. Its positive effects over specific diseases such as Huntington’s, Parkinson, and other neuromuscular dystrophies or diseases are currently under experimental evaluation (Kreider et al. 2017). Caffeine, beta-alanine, aminoacids, and nitric oxide agent in combination have been used for athletes to get synergistic effects in their intensity exercise performance and training adaptation. However, solid experimental conclusions in humans regarding gender difference in supplementation effects are premature and more robust controlled studies are required (Harty et al. 2018).

Proteins intake is also a very popular nutritional ergogenic aid for athletes and was initially recommended inside a range of grams per day depending on weight and age (children,

adolescents, or adults) (Kreider et al. 2017). Muscular temporal recovery in its function is improved after systematic whey protein supplementation. Proteins enhance strength and muscle mass in resistance training (isometric, isokinetic, torque or weight lifting, or isoinertial maximal voluntary contraction) and facilitate restoration of contractile function (Davies et al. 2018). Experimental comparison reported beneficial effects on the muscle function for the group who took proteins compared with the control who did not however, it is surprising that only eight high-quality studies have been published about protein and its effects, over a period of 10 years (Davies et al. 2018).

On the other hand, Magnesium (Mg), which is an essential mineral, is also good to enhance exercise performance. Animal studies have proved Mg might improve exercise performance because of facilitation of the glucose availability in the blood for brain, muscle, and heart. Glucose is converted to pyruvate during aerobic exercise and it is reduced to lactate during anaerobic exercise. Lactate might induce muscle fatigue or laces, and Mg reduces or delays lactate accumulation in the muscle. It also participates in energy metabolism, assisting muscle contraction and relaxation for muscle tissue recovery. In natural food it is found in nuts, seeds, fruits, vegetables, and whole grains. Mg is widely recommended to active and physical competitive athletes and for long-term strenuous exercise (Zhang et al. 2017).

Conclusion

The state of physical health, as the absence of disease, is reached through different cognitive and metabolic ways. Sports, exercise, and physical activities help to maintain the body in all its functions while nutrition, food, and supplements give the energy and compounds required to proper real performance capacities or enhance training adaptations. In this short chapter, we analyzed briefly some of the most interesting topics in the field.

Acknowledgments We thank Prof. Dr. D. F. Swaab because of his example in the method of researching and

studying. Also to Dr. Jenneke Kruisbrink for her kindly scientific literature resource provision. We would like to thank the anonymous reviewer who suggested language style improvements.

Physiological Evidence for Human Sperm Competition

Tara DeLecce

Definition

Humans have experienced sperm competition in their mating history and men have evolved both physiological and psychological adaptations to prevent and correct it; the physiological ones are

focused on maximizing the chances of their own sperm winning the competition to fertilize an egg inside a woman's reproductive tract instead of a rival male.

Introduction

In mammals, paternity is not certain, creating the potential for unwitting paternal investment into genetically unrelated offspring; in humans, non-paternity rates for children that men believed they had sired with their regular partner range from 1.7 % to 29.8 % (Pham and Shackelford 2015). Because cuckoldry is costly in socially monogamous mating systems, men have evolved adaptations to thwart cuckoldry, including adaptations to sperm competition. Sperm competition occurs when a woman copulates with two or more men within a brief time period (about 3–5 days), resulting in the sperm of different males competing to fertilize ova (Pham and Shackelford 2015). These adaptations can be both physiological and psychological. The following discusses empirical evidence for physiological adaptations, namely ejaculate adjustment and semen displacement.

Ejaculate Adjustment

Given the nontrivial costs of producing high-quality ejaculates, one adaptation to sperm competition is strategic adjustment in ejaculate quality (also known as prudent sperm allocation) as a function of the risk of sperm competition (Pham and Shackelford 2015). Although widely studied in many species, investigations of ejaculate adjustment in humans have been limited and infrequent. Baker and Bellis (1993, 1995) collected copulatory ejaculates from heterosexual couples and documented a negative relationship between the proportion of time the couple spent together since their last copulation and the number of sperm ejaculated at the couple's next copulation, as predicted by sperm competition theory.

Ejaculate adjustment has also been documented using other measures of sperm competition risk. Men produce higher-quality masturbatory

ejaculates when viewing images of highly attractive women (indexing greater sperm competition risk) compared to men viewing images of unattractive women (indexing lesser sperm competition risk) (Leivers et al. 2014a). Kilgallon and Simmons (2005) documented that men produce masturbatory ejaculates with a greater percentage of motile sperm when viewing images of one woman and two men (cueing the presence of sperm competition) than when viewing images of three women (cueing absence of sperm competition). Pham et al. (2015) analyzed masturbatory ejaculates along several parameters (e.g., number of sperm, percentage of motile sperm, swimming velocity) and documented that men produce higher-quality ejaculates under a "sperm competition present" condition (men were instructed to imagine sex with their partner for the first time since she admitted to committing an infidelity) than under a "sperm competition absent" condition (men were instructed to imagine sex with their partner for the first time since she admitted to losing some of the couple's money from gambling).

Leivers et al. (2014b) documented that men in committed relationships who reported more "mate guarding" activities (e.g., monopolizing their partner's time) produced lower-quality masturbatory ejaculates compared to men who reported fewer mate guarding activities. Leivers et al. (2014b) argued that men who frequently engaged in mate guarding are at lesser sperm competition risk because they can better account for their partner's activities and, consequently, invest fewer resources into producing costly, higher-quality ejaculates.

Semen Displacement

It has been suggested that the length and shape of the human penis allows for it to displace semen from rival males that may already be present in a woman's reproductive tract and therefore give an advantage in sperm competition (Pham and Shackelford 2015). Consistent with this theorization, men who suspect their regular partner of infidelity or who have spent an extended period of time apart from their partners (another cue of

sperm competition risk) thrust deeper and more quickly during the couple's next copulation, as reported by both men and women (Gallup and Burch 2004). This deeper and quicker thrusting is intended to optimize the chances of displacement of any potential rival sperm that could be in their partner's reproductive tract. Similarly, prolonged duration of copulation has been reported as a semen-displacing tactic (Gallup and Burch 2004). Additionally, men who are at recurrent risk of sperm competition (as measured through their partner's personality traits and attractiveness) perform deeper and more frequent thrusts compared to men who are not at recurrent risk of sperm competition (Goetz et al. 2005).

Even at the commitment level of marriage, one study found that husbands performed more semen-displacing copulatory behaviors during their last sexual encounter when their wife spent more time with male coworkers and friends (i.e., potential rivals that may be a cue to sperm competition risk; Pham et al. 2017). This study also incorporated the variable of discrepancy in sexual interest between spouses as a cue to sperm competition. Specifically, when women engage in extra-pair copulations, they prefer to delay copulating with their regular partner to bias the outcome of sperm competition in favor of the rival male (Pham and Shackelford 2015). Accordingly, Pham et al. (2017) found that the bigger the discrepancy in sexual interest (e.g., wife's interest was much lower than the husband's) the more semen-displacing copulatory behaviors performed by husbands at the couple's last sexual intercourse.

Conclusion

Sperm competition has had a significant influence on the evolution of human mating strategies (Pham and Shackelford 2015). Physiological evidence of this influence is found in men's ability to adjust the quality of their ejaculates based on the risk of sperm competition at each copulation and their deployment of semen-displacing physical actions during copulation to reduce the risk of sperm competition. Compared to psychological

adaptations, men's physiological adaptations to sperm competition are not as well understood, and more research in this domain will improve the knowledge base of how methods to combat sperm competition function in humans.

Definition

The mechanism that carries out a physiological process is known as physiological mechanism.

Introduction

The healthy state of the body depends upon the integrity of various organ systems. The organ systems in the body function in a particular manner constantly. The mechanisms, by which the organ systems of the body function, are often referred to as “physiological mechanisms.” For example, “behavior” of an animal including human beings is one of the functional outcomes of the brain. In other words it can be said that certain neurophysiological mechanisms are responsible for particular behaviors of animals (Barnard 1983).

Physiological mechanisms explain any health-related events or outcomes. Physiological

mechanisms can be altered voluntarily. For example, exercise causes alteration in the cardiac physiology of resting state. A particular posture (e.g., cross-legged posture) may alter the physiological mechanism (increase in blood pressure) (van Groningen et al. 2008). Physiological mechanisms (reproduction, fertilization) are responsible for formation, development, as well as birth of an individual. Multiple physiological mechanisms are responsible for survival of an individual. Successful survival of an individual depends upon optimal functioning of all the organ systems of the body. Healthy state also requires successful combat of the pathogens and other harms that possess threat to the integrity of health. The individual must adapt with the environmental needs from time to time in order to remain healthy. Experiments among animals and lower organisms support that certain physiological mechanisms play pivotal role in acclimatization (Gates and Edmunds 1999). A similar pattern of physiological responses is seen among animals and human beings to adapt to stress (Martin et al. 2011).

Physiological mechanisms may operate in the subcellular (e.g., protein synthesis), cellular (e.g., nerve conduction), organ (e.g., detoxification of toxic metabolites in the liver), as well as inter-organ (e.g., neuroendocrine control of reproduction by hypothalamic-pituitary-adrenal axis) level. The physiological mechanisms operate to maintain the homeostasis in the body.

Physiological Mechanisms: Variations

Physiological mechanisms may vary within the species as well as across the species. For example, respiratory rates vary among mammals; within the species of mammals, respiratory rate also varies at different physiological states (resting state, exercise, during pregnancy). There are also variations in a particular physiological mechanism within a species for a particular physiological state. For example, lactation is a physiological mechanism that operates among mothers to meet the nutritional needs of their offspring; however there are individual variations in lactational physiology (breast development, milk production) among

mothers (Jonas and Woodside 2016). Many biological, psychological (personal), and social factors play crucial role for these variations in physiological mechanisms (Jonas and Woodside 2016). Sex of an individual too plays a role in determining the variations in physiological mechanisms. Evidences support that the experience of respiratory distress (e.g., exertional dyspnoea) differs among males and females (Schaefer et al. 2012). The physiological mechanisms differ between males and females, which specifically regulate the gonadal function and determine masculine and feminine characteristics (Miller 2014). Gender differences are also present in the physiological mechanisms operating to metabolize glucose and fatty acids in the skeletal muscles (Lundsgaard and Kiens 2014). Gender differences are also present in the physiological mechanisms associated with illnesses. For example, autoimmune disorders develop due to alterations in physiological mechanisms, and it is more common among females than males (Blair 2007). Similarly, calcium metabolism and bone mineral density are influenced by gonadal hormones (estrogen, testosterone). Deficiency state of estrogen (e.g., postmenopausal) predisposes to osteoporosis, which is more common in females than males (Blair 2007).

Variations in certain physiological mechanisms occur across the life span of an individual. The physiological mechanisms operating during fetal life change to a different type during infancy, childhood, adulthood, and late life (van Beek et al. 2016).

Physiological Mechanisms: Evolutionary Significance

Evolution brings change in the organism in totality. Various evolutionary processes like natural selection, drift, and sexual selection and various genetic changes are responsible for the changes in the organism. These factors may alter the physiological mechanisms (Feder et al. 2000). The changes in physiological mechanisms are capable of causing changes in the phenotype and genotype too.

Cell is the structural and functional unit of a living organism. The organ physiology depends upon the cellular architecture of the organ. Genes regulate the functioning of the cells to a greater extent. During the process of evolution, changes in the genetic elements happen. The genetic changes across the generations might be an important determinant of changes in the physiology and hence the physiological mechanisms (Ruiz-Mirazo et al. 2017).

Evidences support that social connectedness, bonding, and cooperativeness evolved with time. Certain physiological mechanisms (neuroendocrine and genetic) are responsible for the above social behaviors, which evolved with time to meet the needs of individuals (Taborsky and Taborsky 2015).

Physiological Mechanisms: Health Significance

Healthy state of an individual is determined by the optimal function of the organs of the body. Failure of the physiological mechanisms results in health hazards. Failure in regulation of physiological mechanisms results in development of physical illnesses as well as psychiatric disorders (McGuire and Troisi 1987). Postmortem brain studies suggest that alterations in brain physiological mechanisms result in development of certain psychiatric disorders (Berretta et al. 2015).

Restoration of the physiological parameters restores health, which is mediated through specific physiological mechanisms. For example, electrolyte imbalance (hyponatremia, hypokalemia, etc.) alters the cellular physiology, which in turn alters the electrophysiology of conducting tissues of the body (neurons and muscles), resulting in cardiac arrhythmia, seizure, and delirium. Correction of electrolyte imbalance restores the alterations in physiological parameters and corrects the adverse consequences associated with it.

Similarly, cerebral blood flow is regulated by certain physiological mechanisms (intracranial pressure, blood pressure, cerebrovascular physiology, etc.), failure of which may result in health

hazards or any pathological process that may alter the physiological mechanisms regulating cerebral blood flow (Mchedlishvili 1980).

At times the altered physiological response may indicate some ongoing harmful events. The increased intracranial hypertension secondary to head trauma or intracranial lesions manifests with hypertension, bradycardia, and respiratory irregularities called as “Cushing’s triad.” This altered physiological response may be considered as a clinical indicator for urgent surgical decompression in these patients.

Respiratory illnesses like bronchial asthma are related to failure of physiological mechanisms associated with autonomic regulation (cholinergic mechanism causes bronchospasm and adrenergic mechanism causes bronchodilatation) (Gazzola et al. 2018). This forms the basis of pharmacological management of bronchial asthma (either blocking the receptors producing bronchoconstriction or facilitating bronchodilatation).

Alterations in the physiological mechanisms at a particular stage of life may have association with experiences of earlier life events. Evidences support that early-life adversities have adverse consequences during adulthood. The physiological mechanisms involved in the association of childhood adversities to morbid illnesses in adult life are immune physiology, neuroendocrine physiology, as well as metabolic physiology. Alterations in physiological mechanisms may lead to development of psychiatric illnesses, cardiovascular disorders, metabolic abnormalities, and cancer, which can be traced back to childhood maltreatment and adversities (Berens et al. 2017). There is close association of physiological mechanisms with the psychological well-being. For example, during anxiety, there is heightened autonomic activity, which is manifested in the form of dryness of mouth, palpitation, tachycardia, increased sweating, and tightness of the muscles. Similarly, during depression there is activation of hypothalamic-pituitary-adrenal (HPA) axis. The relationship of physical and psychological well-beings is bidirectional, one affecting the other. It possibly explains long-standing medical conditions (e.g., most of the lifestyle-related disorders)

commonly have comorbid psychiatric disorders like depression and anxiety disorders. On the other way round, psychiatric disorders like depression, anxiety disorders, schizophrenia, and bipolar affective disorder are associated with metabolic syndrome and increased risk of diabetes, heart diseases, as well as stroke.

Physiological mechanisms are targeted in certain therapeutic interventions. Aerobic exercises, relaxation exercises, yoga, meditation, and related activities produce positive health effects by regulating the physiological mechanisms of the body. Biofeedback therapy uses the signals from various physiological parameters (heart rate, temperature, respiratory rate, skin conductivity, muscle contraction, electrophysiology of the brain) and gives feedback to the individual, who attempts to voluntarily control over the altered physiological mechanisms (Jung et al. 2012).

Conclusion

Many alterations in the physiological mechanisms of the body can be altered through lifestyle modifications. Hence, lifestyle-related disorders and many other noncommunicable diseases can be prevented by healthy lifestyles. Understanding the physiological mechanisms will help in the prevention of illness and restoration of wellness.

Physiology of reading processes; Physiology of speech articulation; Physiology of speech perception

Definition

Physiology of language refers to the organic processes and phenomena associated with speech perception, articulation, and reading.

Introduction

Comprehending and producing linguistic utterances relies on complex phonological, syntactic, and semantic representations that we incrementally and unconsciously build as the message unfolds in time. Behind these cognitive mechanisms there are physiological processes that drive visual and acoustic perception of linguistic stimuli and the production of sounds. In the following, the main principles underlying the physiology of speech perception and articulation as well as of reading abilities will be described.

Physiology of Speech Perception

Speech perception can be defined as a series of computations that take continuously varying acoustic waveforms as input and output discrete representations that are mapped onto lexical representations stored in long-term memory (Poeppel et al. 2008). It is known from linguistic research that mapping sound to meaning is a process that spans across several levels of representation and analysis. The smallest unit of analysis of the acoustic signal is represented by features, which reflect the articulatory basis of speech and encode independently controllable aspects of speech production, (e.g., $[\pm\text{voice}]$ indicates laryngeal involvement). Combinations of features make up segments, i.e., individual phones like $[p]$, $[s]$, or $[t]$. Segments that contrast with each other in nearly identical environments are called phonemes, such as $[t]$ and $[p]$ in *ten* and *pen*. In turn, phonemes are organized in syllables, the structure of which presents language-specific properties. Featural, segmental, and syllabic levels of analysis provide the infrastructure for prelexical phonological analysis and a prerequisite for mapping sound to meaning.

Central in speech perception research is the study of how listeners are able to identify and recover the sequence of phonetic segments that compose words and phrases, to ultimately comprehend a spoken utterance. Besides cognitive mechanisms, this engages complex processes at the physiological level. Thanks to modern

electrophysiological and neuroimaging techniques, much has been learned about the auditory areas and processing correlates associated with speech perception (see Friederici 2002, 2011 and Price 2012 for a review), but the understanding of the basic physiological and brain mechanisms of auditory processing still rests on animal (i.e., non-human primates) models.

Sound carries energy through the air at a speed of 340 m/s: ears capture this energy and transduce it into electrical signals that are analyzed by the nervous system. The first structure involved in this complex process is the external ear, which captures sound and channels it to the tympanum (or eardrum). The mechanical energy carried by air determines the motion of three small bones in the middle ear – the malleus (or hammer), the incus (or anvil), and the stapes (or stirrup). In particular, the stapes acts as a piston that pulls and pushes cyclically on the fluid-filled compartments of the cochlea in the inner ear.

Since the days of Helmholtz (1885) and Von Békésy (1960), it has been known that sound reaching the tympanic membrane triggers a traveling wave along the basilar membrane of the cochlea. This membrane acts as a mechanical frequency analyzer that distributes energy to hair cells arranged along the membrane length, based on the various tones that make up the acoustic stimulus. Low frequency sounds excite basilar membrane motion near the apex, where the membrane is thicker. Medium-frequency sounds excite the membrane in its middle, while high-frequency sounds excite the base of the membrane, where it is thinner.

Hair cells in the membrane transduce the basilar membrane oscillations into receptive potentials, and the neurochemicals that are released are picked up by the neurons of the eighth cranial nerve, which terminates in the cochlear nuclear complex in the brain stem. The complex auditory pathways of the brain stem mediate functions such as the localization of sound sources and the forwarding of auditory information to the primary auditory cortex (also called A1), in Heschl's gyrus. This region contains tonotopic maps, with neurons tuned to low frequencies arrayed in the rostral end of the area and those tuned to high frequencies at the caudal end.

The primary auditory cortex is surrounded by several distinct regions involved in the elaboration of specific types of acoustic information. Recent functional neuro-imaging studies have shown that auditory processing of speech and nonspeech stimuli activates the superior temporal gyrus bilaterally (Friederici 2011; Hickok and Poeppel 2007; Price 2012), including and surrounding Heschl's gyri. In contrast, selective activations to phonological analysis of speech sounds have been found both in the posterior portion of the left superior temporal gyrus and in the left inferior frontal and premotor areas, typically associated with articulatory processes, thus suggesting a tight interaction between acoustic and articulatory processes.

Successful mapping of familiar sounds to meanings (at the word and sentence level) has been shown to involve several left-lateralized areas. Recently, Hickok and Poeppel (2007) have proposed that mapping of sound to meaning involves a ventral stream that extends from the middle and posterior portion of the superior temporal sulcus bilaterally to the left anterior portion of the middle temporal gyrus. Moreover, anterior temporal areas appear to be recruited in accessing increasingly specific semantic associations, with activations for sentences and narratives extending to the temporal pole. In contrast, ventral inferior frontal regions, such as the pars orbitalis and triangularis, seem to be engaged in operations of selection and retrieval of semantic representations (Zhuang et al. 2011; Whitney et al. 2011).

Electrophysiological and magneto-encephalographic studies have shown that acoustic-phonological analysis of the input takes place as early as 100 ms after stimulus onset, as evidenced by two early negative components – the N1 and the mismatch negativity – associated with discrimination of vowel category perception (Näätäneiv et al. 1997; Obleser et al. 2006, see Luck 2014 for a review of auditory components). Their neural sources have been located in or close to the primary auditory cortex, suggesting that these processes occur at the earliest stages of speech perception.

Lexical analysis of the acoustic input is reflected by another electrophysiological

component peaking around 400 ms post-stimulus onset – the N400 (Kutas and Federmeier 2009 for a review) – the neural sources of which have been identified in the posterior portion of the temporal cortex (Lau et al. 2008). Moreover, the same component has been found to reflect processes of discourse integration at the sentence level (Halgren et al. 2002; Lau et al. 2008; Mancini et al. 2011; Tse et al. 2007).

The analysis of the syntactic structure underlying sentences has been associated with both early and late electrophysiological components. An influential model of auditory sentence comprehension (Friederici 2002, 2011) proposes that processes related to phrase-structure building are reflected in early left anterior negative (eLAN) effects, arising as early as 150 ms post-stimulus onset. Phrase-structure building mechanisms are followed by the establishment of grammatical relations, such as agreement between subject and verb, and would be reflected by anterior negative effects (left anterior negativity, LAN) between 300 and 500 ms. In the same temporal window, the elaboration of semantic relations among sentence parts would take place, as evidenced by N400 effects in response to thematic role assignment anomalies. Finally, the P600 component reflects the integration of formal and semantic information to assign an overall propositional meaning to a sentence. It should be noted that the functional interpretation of the P600 has changed over time. Initially thought to reflect processes of syntactic reanalysis, repair, and integration (see review in Hagoort et al. 1999), it has been more recently associated with a wider range of linguistic manipulations, ranging from conflicts in the semantic-thematic fit between predicates and arguments (the so-called semantic P600 effect, see Kuperberg 2007 for a review) to domain-general conflict monitoring operations (van den Meerendonk et al. 2009).

Physiology of Speech Articulation and Production

Articulation refers to the process by which speech sounds are formed and produced. From a

physiological point of view, articulation is the result of the coordination of muscles in the respiratory, laryngeal, and articulatory systems. These systems regulate three basic processes involved in sound production: the generation of air pressure in the lungs, the regulation of vocal folds vibrations in the larynx, and the control of resonance in the articulatory system.

Prior to initiation of speech, during *inhalation* (or inspiration), thorax and lungs expand, resulting in the pressure inside the lungs dropping below atmospheric pressure. It is through air inflow that the two pressures are maintained at equivalent levels. During speech, lungs pressure is maintained nearly constant thanks to the action of inspiratory muscles that prevent excessive airflow and keep a long expiratory phase. In contrast, during *exhalation* (or expiration), the thorax reduces its expansion, resulting in an increase of pressure inside the lungs. As lung pressure is higher than the atmospheric pressure, air flows out. Inspiration and expiration comprise a respiratory cycle. At rest, between 12 and 15 respiratory cycles per minute occur. During speech (also called phonic respiration), inhalation time is reduced while exhalation time is prolonged.

The air that is exhaled passes through several parts of the respiratory tract, such as the trachea and the larynx. The larynx is a sound producing organ that contains two pyramid-shaped muscles – the vocal folds – the vibration of which allows voice production. Four stages are involved in voice production, each of which comprises different positions of the vocal folds and different levels of air pressure in the larynx. During *closure*, vocal folds are brought together by laryngeal muscles. The accumulation of air below the folds (called subglottal pressure) produces a *compression* that forces vocal folds apart, leading air to flow out during the *release* stage. During speech, vocal folds vibration does not remain constant but is controlled by the speaker, based on his/her articulatory intentions. Increase in the frequency of vibrations determines voice pitch increase.

Speech articulation relies on processes carried out during the expiratory phase and consists of continuous changes in vocal fold vibration. Articulatory organs alter the resonance of the vocal

tract, making it possible to produce consonant sounds of different types. The most important articulator is the tongue, the deformation and movement of which determine vowel quality and the production of certain consonants: palatals (y in “yes”), velars (g in “guy”), and pharyngeals (typical of Arabic dialects). Dental (t in “time”), alveolar (s in “soap”), and retroflex consonants (r in “North America”) depend on the movement of the tongue blade and apex. Lips assist in the production of labial consonants (b in “beer”) and vowels (like u), while the velum controls opening and closing of the velo-pharyngeal port, allowing for the distinction between nasal and oral sounds. Articulation of vowels and back consonants (consonants articulated in the velum and farther back) engages pharyngeal muscles, which contract and thus adjust the width of the pharyngeal cavity.

As speech articulation involves the sequencing of a series of sound events, it often results in the articulation of one sound affecting that of another sound. This process is known as *coarticulation*. An example of coarticulation is represented by the production of the sound [k] before the vowel [i] in English, such as in *keys*, or the [k] sound articulated before [ow] in words like *cold*. In the first case, the place of articulation of [k] is palatal, while the second [k] is articulated farther back and gives rise to a velar sound. These adjustments are made before the articulation of the vowel in question and can extend across syllables and word boundaries.

A number of techniques have been developed to study speech articulation. One of these is palatography, which consists in recording contacts between the tongue and the palate to get articulatory records for the production of speech sounds (see Ladefoged 1997 for a description of the technique). Marker-tracking techniques include X-ray microbeam systems, which track small metal pellets attached on the articulatory organs, and magnetic sensing systems, which use small sensor coils to detect alternate magnetic fields with different frequencies.

Neuro-imaging studies have also been profitably employed in the study of speech articulation. The processes involved in speech production

largely overlaps with the mechanisms engaged in speech comprehension (Price 2012): sub-articulatory processing may be involved in discriminating auditory words, while auditory images may be automatically involved in articulation. In line with this, it has been suggested that a dorsal stream projecting from the superior temporal gyrus towards inferior parietal and posterior frontal lobe regions could be involved in auditory-motor integration, by mapping acoustic speech sounds to articulatory representations Hickok and Poeppel (2007). The overt articulation of speech sounds also involves sensorimotor activity in the pre- and post-central regions that control orofacial muscles as well as thalamic and left insula regions for the control of laryngeal activity, phonation, and breathing (Price 2012).

Physiology of Reading

For millions of years humans have spoken and understood language, but their ability to read has developed relatively recently (about 5000 years ago). From a psycholinguistic perspective, reading has been therefore considered as a secondary process that recruits neural circuits and mechanisms previously developed during the learning of auditory language. In line with this evolutionary view, results from a number of neuro-imaging studies have evidenced that there are no brain areas specific to reading. Rather, learning to read implies establishing associate connections between object processing areas in the visual cortex and speech processing areas in the temporal and frontal cortices (Price et al. 2001). Three specific processes are associated with reading that differentiates it from spoken language comprehension: the identification of visual features that are relevant to define letters, the subsequent identification of the whole word form, and the conversion of orthographic to phonological information.

Readers go through a text with rapid movements – *saccades* – that bring peripheral visual input onto the central part of the eye retina, the fovea. Between saccades, *fixations* occur, during which the eyes remain relatively still on a word for

about 200–300 ms. The average duration of a saccade during reading is about 30–50 ms, while the time it takes to plan and execute a saccade (latency) is about 150–175 ms (although both latency and duration can change depending on whether reading is silent or oral, see Rayner 1998 and Rayner and Castelhan 2007 for an overview), which suggests that saccade programming could be done in parallel with comprehension processes in reading (Rayner 1998). Eyes are never completely still, and other types of small movements occur during fixations. A constant tremor of the eyes (the *nystagmus*) serves to keep the nerve cells of the retina firing, while small and slow *drift* movements are thought to be due to an imperfect control on the oculomotor system by the central nervous system. To bring the eyes back to where they were before the drift, small and rapid eye movements, called micro-saccades, occur (a thorough review can be found in Gilchrist, 2011 and Martinez-Conde et al. 2009).

Visual processing begins in the retina. Light, focused by the cornea and the lens, traverses the vitreous humor that fills the eye cavity and finally reaches the retina and the fovea. Subsequently, it is absorbed by visual pigments in the photoreceptors, triggering a series of neurochemical reactions that lead to a change in the membrane potential of these cells.

The output of the retina is conveyed by ganglion cells, which depart from the optic disc and form bilateral optic nerves that project to the optic chiasm. Optic nerves project to three main subcortical areas: the pretectum and the superior colliculus in the midbrain, and the lateral geniculus nucleus in the thalamus, each of which has a specific function. The retinal projection to the pretectal area is important for pupillary reflexes: for example, when light shines in one eye, its pupil gets constricted, and so does the pupil of the other eye. Saccadic eye movements are controlled by projections to the superior colliculus, while the lateral geniculus nucleus represents the main subcortical structure that carries information to the primary visual cortex.

In the primary visual cortex (also called V1), located in the calcarine fissure of the occipital

lobe, low-level perceptual analysis is carried out: the outlines of a visual image are analyzed and decomposed into segments of various orientations, like horizontal or vertical lines.

Some authors have argued that visual information resulting from low-level sensory analysis carried out in the primary visual cortex enters the so-called Visual Word Form Area (VWFA, Cohen et al. 2000; McCandliss et al. 2003; see Price 2012 for a review) in the left occipitotemporal cortex. A wealth of studies agree that this area is consistently activated by visual word processing across languages and orthographies, that activation is higher for written than spoken words, and irrespective of case and font of the letters. However, more recent findings point to a functional parcellation of the ventral portion of occipitotemporal cortex, with more posterior areas involved in visual feature extraction, while more anterior ones would subserve lexico-semantic processing of whole words (Price 2012).

Electrophysiological studies on word reading report the presence of a series of early components typically related to the analysis of the features and parameters that characterize a visual stimulus, such as words, faces, and pictures in general (see Pratt et al. 2011 for a review of sensory electrophysiological components): the P1 (a positive component peaking about 110 ms after stimulus onset); the N1/N170 (a negative component peaking about 180 ms after stimulus onset, see Rossion and Jacques 2011), and the P2 (a positive component peaking about 280 ms post-stimulus onset). Of particular interest is the N170, typically associated with expert scrutiny of face (Carmel and Bentin 2002), which has been recently reported in studies comparing the effects of orthographic and nonorthographic processing (see Maurer and McCandliss 2008 for a review).

Conclusions

The study of language and of the mechanisms underlying its processing has advanced significantly and steadily over the last years, thanks to cutting-edge techniques and experimental paradigms that have made it possible to observe

physiological processes and neuro-anatomical substrates in controlled laboratory settings. Nevertheless, several challenges remain to be faced, the most important of which is arguably represented by the study of these mechanisms in the most ecologic and naturalistic setting, namely human-to-human interaction.

Pidgins and Creoles

Definition

A pidgin is a mixed language that emerges as a new medium of communication among speakers with distinct first languages.

A creole is a nativized mixed language.

Introduction

This chapter focuses on theories of creole genesis, elaborating on various scenarios accounting for the emergence and development of creole languages. First, we draw a distinction between pidgins and creoles and discuss the connections between the two, including the supposed pidgin-

to-creole cycle. Then, we introduce the superstratist, substratist, and universalist views of creole genesis and elaborate on the most recent theories that instantiate these different positions. We focus on processes of second language acquisition (Plag 2008), relexification (Lefebvre 1998), language creation (Baker 1994), and feature recombinations (Mufwene 2001; Aboh 2006).

On the Nature of Pidgins and Creoles

Pidgin and creole languages are considered “mixed” languages in the sense that they cannot be traced back to a single earlier language (Thomason 2008, p. 271), due to the multilingual context in which they emerge. These languages typically develop in plantation, trade, and other work settings where speakers with different first languages (henceforth, L1s) are in contact with each other for an extended period of time and create a new language for the purpose of communication.

It is often assumed that in the beginning stages of interaction between speakers with distinct L1s, they create a rudimentary pidgin that turns into a creole after it becomes nativized, meaning after it acquires native speakers. As with any natural language, creoles are elaborate, sophisticated, and complex linguistic systems, in comparison to pidgins. As a result, some creolists view adults as the original creators of pidgins and children as the creators of creole languages.

Things are not, however, that simple as the pidgin-to-creole cycle, and the nativization criterion are not generalizable to all cases of creole formation. On the one hand, there is indeed evidence that some creoles like Hawaiian creole first developed as a pidgin (Hawaiian Pidgin English) spoken by the Japanese, Portuguese, and Tagalog plantation workers (among others) before it became nativized and turned into Hawaiian Creole English (Bickerton 1984). On the other hand, there is no evidence that creoles in the Caribbean for instance (i.e., Jamaican) have been through a pidgin phase, suggesting that both children (in the Hawaiian case) and adults (in the Jamaican case) can be agents of creolization. Numerous factors

such as population demographics, settlement vs. plantation colonies, access to the dominant language, and power relations between the languages in contact may determine whether adults or children are the original contributors to creolization. In sum, this greatly depends on the socio-historical context in which a given creole emerges. Also, it is not always the case that pidgins are deprived of native speakers. Indeed, the extended pidgin Tok Pisin (in Papua New Guinea), which has been in use for a long period of time over a large territory, has now developed native speakers and can no longer be considered a pidgin by the strict definition of the term.

On the Superstratist, Substratist, and Universalist Views of Creole Genesis

As for the linguistic properties of creole languages, scholars agree that their lexicon is mostly derived from the superstrate (the socioeconomically dominant language). There is, however, no consensus as to the source of their grammatical structures. Some scholars argue that most of the grammatical structures found in a given creole derive from the superstrate that contributed to its genesis; this is the superstratist view. In contrast, other linguists believe that the original creolophones' first languages (substrates) mostly contributed to the grammatical structure of creoles; this is the substratist view. Finally, there are linguists who believe that it is not the source languages but rather language universals that are responsible for their most salient grammatical traits. This view rests on the assumption that creoles share similar properties and that children are the primary agents. Bickerton (1984) has proposed that due to the chaotic linguistic environment in which the original creolophone children are born, they cannot rely on consistent, stable input from a given language to proceed with a regular type of acquisition. Consequently, these children are dependent on a language bioprogram which is a biological blueprint consisting of unmarked settings. This is the universalist view. Bickerton offers a cluster of linguistic properties

that he argues are found in the most radical creoles. He claims for instance that tense, mood, and aspect markers (among other features), typically found in preverbal position (see the aspect marker *sta in* (1)), are signs of the bioprogram. Such markers convey temporal, modal, and aspectual meaning and appear just before the verb, rather than as inflections on the verb stem, as in Portuguese (2):

- (1) *N sta bai kaza.* (Cape Verdean Creole)
I ASP go home
"I am going home."
- (2) *Será que você iria para a sua casa.* (Portuguese)
be+Inflection that you go+Inflection for your house
"May be you would go home."

Similar views arguing for a creole prototype can be found in McWhorter (1998) and Bakker et al. (2011), among others.

Current Theories of Creole Formation: The Interlanguage Hypothesis, Relexification, Language Creation, and Feature Recombinations

We now delve into current theories, which build on the positions just discussed. For Plag (2008), the genesis of creoles is linked to processes of second language acquisition, as he views them as conventionalized interlanguages of an early developmental stage. According to this view, labeled the "interlanguage hypothesis," some creole properties such as SVO word order, preverbal negation, and sentence-initial *wh*-words can be best accounted for in light of processability. Plag backs this proposal by referring to developmental stages in English interlanguage syntax which typically displays the canonical word order SVO, as in "Bob kick ball", preverbal negation as in "he no like coffee" and the sentence-initial *wh*-word as in "where is John?". The fact that the set of creoles Plag examines shares the same features as interlanguage syntax led him to propose that

creoles are conventionalized interlanguages but this view is problematic on two fronts:

- (a) For processes of second language acquisition to be involved, one would have to assume that early creolophones had access to the superstrate. If this is the case, why don't we observe properties across creoles that reflect more consistently the features of their respective superstrate in the domains of word order, negation, or *wh*-words among others? What happens in the cases where the length of contact between early creolophones and colonists were fairly short due to massive influxes of slaves on sugar or cotton plantations? This would mean that the majority of the population would not have had access to the superstrate, hence second language acquisition would not have happened.
- (b) The "interlanguage hypothesis" also implies that interlanguage features can be found in the majority of creoles. This is not the case, based on the *Atlas of Pidgin and Creole Structures* (Michaelis et al. 2013) which reports a number of creoles as departing from the typical SVO word order and as displaying sentence-final *wh*-words, and sentence-initial or sentence-final negators, contrary to the predictions of the interlanguage hypothesis.

Another theory of creole genesis is relexification (Lefebvre 1998), which assumes that a creole lexicon originates from the superstrate but its syntax and semantics have their source in the creole substrates. This division of labor is represented in the schema in (3) which conveys that the lexicon (or phonology) of the original speakers' L1 was replaced by the lexicon of the superstrate but the semantics and syntax of their L1s were preserved.

- (3) /phonology/i/phonology/j
[semantic feature] i
[syntactic feature] i (Lefebvre 1998: 41)

This is illustrated in the Haitian "weather" expression in (4). The Haitian

weather construction is parallel to its Fongbe counterpart in (5) but distinct from its French equivalent in (6). Such examples allow Lefebvre to propose that the Haitian lexicon originates from French, whereas the syntax and semantics were derived from Fongbe:

- (4) *Lapli tonbe*. Haitian (Lefebvre 1998: 72)
Rain fall
"It is raining."
- (5) *Ji ja*. Fongbe (Lefebvre 1998: 73)
Rain fall
"It is raining."
- (6) *Il pleut*. French (Lefebvre 1998: 73)
It rain
"It is raining."

This theory has been criticized for granting too much importance to the grammar of the speakers' L1 at the expense of the superstrate's. It also postulates a clear-cut division of labor that is not always observable, as substrates can contribute to the lexicon of a creole and superstrates to its grammar and semantics. Relexification is considered a substratist theory.

The third theory we examine is language creation, as presented in Baker (1994). According to this theory, the original creole speakers were not motivated to target the superstrate, their main priority being to simply devise a "medium of interethnic communication" (Baker 1994). As the superstrate was not a target, this would account for the original speakers' creativity, as they did not replicate nor transferred faithfully the features in the source languages to the creole but instead fostered innovations that cannot be found in any of the languages in contact. For instance, speakers avoided homophony in Mauritian Creole by designing a lexicon where the use or absence of determiners helped distinguish between two words that would otherwise be homophonous in the language. For instance, in (7a), the word for "health" is distinguished from the word for "song" in (7b) by appending the definite determiner *la* to *santé*.

- (7) a. *lasanté* “health” (Fr. la santé) (Baker 1994: 72)
 b. *santé* “song” (Fr. chanter, v.)

Such innovations are not traceable to any of the source languages and led Baker (1994: 75) to argue that this is an evidence that original creolophones were more involved in creating a new language for the purpose of communication than in learning a second language.

We now turn to the theory of feature recombinations. Developed within a framework of competition and selection (Mufwene 2001), this theory is meant to illustrate the competition between features from distinct source languages, resulting in winners and losers. We consider below examples from Aboh (2006) in which he analyzes how features are recombined, proposing a modular view of feature transmission. According to this view, features from the languages in contact can recombine following a variety of paths. In some cases, the semantics and syntax of a given feature originate from the same source; in other cases, the semantics of a feature comes from the superstrate and the syntax from the substrate(s) or vice-versa. Specificity in Haitian Creole illustrates a case where the syntax and semantics of a feature come from a single source: Haitian uses a demonstrative realized as *a* or *la* to express specificity; such a marker appears to the right of the noun (8a). Gungbe (one of Haitian Creole’s substrate) also uses a specificity marker to the right of the noun (Aboh 2006), as in (8b). In both languages, the marker refers to an aforementioned entity. In contrast, the French determiner in (8c) appears in a pre-nominal position (to the left of the noun) and may refer to an aforementioned entity *or* to the entity the speaker and hearer know of (Aboh 2006: 225). Due to the exact parallelisms in syntax and semantics between Haitian and Gungbe, Aboh proposes that Gungbe is the source of both the semantics (marking specificity) and of the syntax (post-nominal position) of the marker *a/la* in Haitian Creole.

- (8) a. *Pè-a* (Haitian Creole)

Priest-Det

“The aforementioned priest”

*“The priest that we know of”

- b. *Mɔpɛ ɩ* (Gungbe)

Priest-Det

“The aforementioned priest”

*“The priest that we know of”

- c. *Le prêtre* (French)

“The aforementioned priest”

“The priest that we know of”

Conclusion

In conclusion, the different scenarios of creole genesis delineated above are tenable if one refrains from generalizing them to all creoles. For instance, the feature recombinations analysis seems quite valid in accounting for features of Haitian Creole but may find limitations in accounting for creoles that have remained in close contact with their lexifiers, resulting instead in a situation akin to second language acquisition (Chaudenson 2001). It is difficult to generalize a given scenario to all creoles because they have distinct demographics, histories, lengths of contact between the source languages, and different power relations between source languages. Scholars should therefore take such variables in consideration before proposing which of the scenarios presented above best accounts for the development of the creole they examine. In sum, the history of a given creole determines which scenario best fits its development.

Definition

A popular science text in evolutionary psycholinguistics asserting the innateness of language in humans and the theory that grammar reflects the linguistic organization of the mind.

Introduction

The Language Instinct is a wide-ranging book on language by cognitive psychologist Steven Pinker. The book gives an account of how the brain acquires and understands language and addresses various topics in linguistics and evolutionary psychology, such as the existence of universal features of language and the possible genetic basis of linguistic ability in humans. Throughout the book, Pinker asserts that the science of language can provide key insights into human cognition.

Pinker argues for a “nativist” view of language development, whereby the ability to acquire language is innate. On this view, humans possess a “mental module” specifically dedicated to learning language and understanding natural speech. Drawing on the theory developed by linguist Noam Chomsky, Pinker asserts that all humans are equipped with a Universal Grammar, which

explains how young children are able to extrapolate grammatical rules to form and understand novel sentences. The nativist position typically opposes the “blank slate” or “empiricist” thesis, which broadly states that people are born knowing nothing but are capable of learning anything.

Throughout *The Language Instinct*, Pinker refutes several common misconceptions about language, such as the belief that in general peoples' grammar is poor and language is deteriorating, that human thought is constrained by language, and that language must be explicitly taught to children.

Universal Grammar and Innateness of Language

Citing work done by Chomsky and experimental psycholinguists, Pinker argues for the universality of language and grammar in neurologically normal individuals. Pinker first notes that no mute civilization has ever been discovered; moreover, all languages, as well as dialects, exhibit complex grammatical structure.

Second, the phenomenon of creolization, or the standardization of a grammar-less pidgin language, suggests that children are able to “inject grammatical complexity where none existed before.” Pinker cites studies by Derek Bickerton on communities of immigrant laborers brought to work on Hawaiian sugar plantations. Having no shared language, the laborers developed a makeshift “pidgin” language, devoid of consistent word order, tense and logical markers, or complex structure. Yet children exposed to the pidgin used standardized grammatical markers in their speech that were both absent from the pidgin of their parents and distinct from the language of the colonizers, thus inventing Hawaiian Creole (1981, 1984). Grammatical standardization can also be observed in deaf children, as, for example, in the case of Nicaraguan Sign Language: younger children who were exposed to the pidgin signing of older children spontaneously introduced grammatical devices absent in the earlier version of the signing system (Kegl and Iwata 1989).

Third, the human brain must be using a mental algorithm to understand and construct new sentences, as opposed to building a “repertoire of responses” learned through rote memorization. Only the existence of a mental grammar explains why children are able to quickly learn the language of their parents, draw reliable conclusions about the meanings of new words, and generalize rules of grammar to produce new constructions which they have never heard (a line of reasoning which Chomsky called the “argument from the poverty of input”).

Pinker notes that the way mothers often speak to their infants, a style of speech he calls *motherese*, is devoid of constructions children are already able to grasp in early childhood, such as turning sentences with two auxiliaries into questions – for example, “A unicorn is in the garden” to “Is a unicorn the garden?” Therefore, these grammatical intuitions cannot have been learned from the child's environment.

The Myth of Degenerating Language

In the chapter titled *Language Mavens*, Pinker describes the arbitrary origins of many “rules” of style and syntax often promoted in writing manuals. Pinker demonstrates that the manipulations of language deplored by “legislators of ‘correct English’” are not only logical, but often serve to make language more rather than less complex. For example, converting nouns to verbs (i.e., *grandstand*, to *grandstand*) admits of an addition to the “mental dictionary,” since verbs constructed from nouns adopt regular conjugations, even when the verb base is itself an irregular verb (i.e., *he grandstanded*, not *he grandstood*). Meanwhile, the root noun retains its function as a noun.

Citing linguist William Labov (1969), Pinker also illustrates that dialects that deviate from the standard grammar of a language are no less grammatical, and they only employ modified grammatical rules. As an example, Black English Vernacular (BEV) possess a full inventory of rules for grammatical manipulations such as forming contractions, inverting sentences, and inventing subjects and auxiliaries (i.e., *Don't nobody know*).

Mentalese

In the chapter titled *Mentalese*, Pinker refutes the hypothesis that thought is identical to or constrained by language, a theory called “linguistic relativism,” or “linguistic determinism” and famously associated with linguists Edward Sapir and Benjamin L. Whorf (Carroll 1956; Kay and Kempton 1984). “People do not think in English or Chinese or Apache,” says Pinker, “they think in a language of thought,” which he calls *mentalese*. Pinker argues that this language of thought is a symbolic system, whose parts can be arranged and rearranged to produce intelligent conclusions, but that these symbols are not necessarily linguistic.

Pinker illustrates the distinction between language and thought by demonstrating that our ability to communicate or compute meaning from sentences is not constrained by the limitations of a given language: a speaker may use a phrase with an ambiguous word, but the underlying idea is *not* ambiguous. Similarly, readers are able to overcome ambiguities in speech or in written text, as in the headline “Drunk Gets Nine Months in Violin Case” (Seidenberg et al. 1982).

Design of Language

Pinker notes that a remarkable feature of grammar is that it allows an infinite number of possible sentences to be constructed from a finite set of symbols. Grammar can thus be described as a “discrete combinatorial system” (Chomsky 1991).

In the chapters *How Language Works* and *Words, Words, Words*, Pinker introduces theories of phrase structure and word structure, illustrating certain universal rules for forming sentences (Jackendoff 1977) and words. Pinker then discusses results from studies in psycholinguistics and cognitive neuroimaging that recommend these theories as models for the mental representation of language. Psycholinguist Peter Gordon, for example, showed that children intuitively reason that compound words can be formed from irregular plural nouns, but not from regular plurals

(i.e., *mice-infested* and *rat-infested*, but not *rats-infested*) (1986).

In another study, ambiguous words or parts-of-speech were shown to activate multiple meanings in the brains of listeners, suggesting that a “mental parser” searches through possible interpretations of words in real time before selecting the correct one for a given context (Swinney 1979).

Evolution and Language

Pinker deviates from Chomsky's position on the human language faculty in that he believes evolutionary theory can explain the development of the language instinct in modern humans.

Pinker applies concepts from Darwinian theory to address several questions about language, such as (i) why there exists a critical period for language acquisition, after which language acquisition becomes significantly more difficult or impaired; (ii) why language is unique to humans; and (iii) why there exists more than one language.

- (i) The critical period for language acquisition can be explained, Pinker says, by considering the benefits and costs of maintaining a mechanism for language acquisition: the skill confers an overwhelming benefit for a young individual, but incurs a great metabolic cost. Once language has been acquired, the skill becomes superfluous.
- (ii) Pinker argues that language, though not communication, is unique to humans in the modern animal kingdom. Despite the efforts of animal researchers to “translate” chimpanzee signing, for example, chimpanzee communication remains devoid of basic features of language such as syntax or vocabulary. (Terrace et al. 1979).
- (iii) According to Pinker, the proliferation of languages across the globe is explained by three major processes: linguistic innovation (the combinatorial creativity of language), the ability to learn, and migration (by which populations diverge over time). However, the similarities among different languages far outnumber, according to Pinker, the

differences between them. Paraphrasing Chomsky, he notes, “a visiting Martian scientist would surely conclude that aside from their mutually unintelligible vocabularies, Earthlings speak a single language.”

Conclusion

Pinker’s *The Language Instinct* has remained an influential work in popular psychology and is still among his best-known publications. Many of the concepts introduced in the book, including the innatist argument for language development, theories on word and phrase structure, and the fallacy of linguistic determinism are addressed in greater detail in subsequent books *Words and Rules: The Ingredients of Language* (1999) and *The Stuff of Thought: Language as a Window into Human Nature* (2007). Pinker’s opposition to the empiricist view of language development and the “Standard Social Science Model” of human nature is also a major focus of *The Blank Slate: The Modern Denial of Human Nature* (2002).

A recent edition of *The Language Instinct*, published in 2007, includes an additional section after the main text in which Pinker revisits each chapter and briefly discusses new research or addresses public and critical reception on the ideas presented.

Placental Proteins in Semen

Rebecca L. Burch
State University of New York at Oswego,
Oswego, NY, USA

Definition

Seminal fluid contains dozens of compounds that affect male fertility, but may also affect female reproduction and physiology. Pregnancy related compounds have been discovered in seminal fluid

and appear to affect the female immune response and embryo implantation.

Introduction

Semen is a reproductive fluid, and as such it has been selected over generations to not only transport sperm, but also increase the probability of conception and maintain a resulting pregnancy (Burch and Gallup 2006). Researchers in the past 30 years have learned that seminal fluid contains ovulation induction factors, immunosuppressants, endogenous opioids, stress hormones, myotonia enhancing compounds, affiliative hormones, pregnancy maintaining hormones, and potential mood enhancing hormones and neurotransmitters (Burch and Gallup 2006; Gallup et al. 2002). Researchers have also administered many of these hormonal compounds through the vagina and determined high levels of absorption that elevated blood levels for hours after administration (Villanueva et al. 1981; Schiff et al. 1977).

Seppälä et al. (1985) found a number of pregnancy associated proteins in follicular fluid and seminal plasma. Since then, a variety of placental and pregnancy related proteins and compounds, including human chorionic gonadotropin (de Medeiros et al. 1992; Asch et al. 1984), human placental lactogen, pregnancy-specific beta 1-glycoprotein, placental proteins 5, 12, and 14 (Seppälä et al. 1985), pregnancy associated plasma protein (Bolton et al. 1986), relaxin (MacLennan 1991), vasopressin (Ney 1986), and ferritin (Brotherton 1990) have been found in human seminal plasma. In many cases their concentrations in follicular fluid and seminal plasma greatly exceeded those in the serum of non-pregnant women or men, and sometimes they even exceeded pregnancy levels (Seppälä et al. 1985). Concentrations of beta- human chorionic gonadotropin and luteinizing hormone were highly correlated with the numbers and motility of sperm in ejaculates (de Medeiros et al. 1992). The levels of placental protein 5 in seminal plasma showed an association with sperm motility, suggesting that placental protein 5 may have a significant biological function in the maintenance

of sperm motility (Lee et al. 1983). Clearly, researchers have concentrated on how these compounds affect male fertility, but it is also possible that levels of ovulatory hormones, human chorionic gonadotropin, pregnancy related proteins, and other compounds can increase the probability of conception and pregnancy maintenance in women.

Relaxin is a polypeptide hormone produced in the human female by the corpus luteum and decidua during pregnancy. In the male, it is produced in the prostate and is present in human semen (MacLennan 1991). According to Stewart et al. (1990), relaxin is significantly elevated 9–10 days following ovulation in women and also increases 1–2 days prior to the first detectable increase in plasma human chorionic gonadotropin during pregnancy. Relaxin may have significant roles in sperm motility, fertilization, implantation, uterine growth and accommodation, the control of myometrial activity to prevent preterm labor, cervical ripening and the facilitation of labor (MacLennan 1991; Weiss 1995). Its role in pregnancy maintenance has yet to be fully elucidated, but relaxin in seminal plasma may act to manipulate the female reproductive cycle or facilitate pregnancy.

Hamberg and Samuelsson (1966) isolated the presence of 13 different prostaglandins in human semen over 50 years ago, but little research has focused on each. The most notable prostaglandins have been shown to be absorbed vaginally, namely E1, E2, and F2 α and more rapidly than other methods of administration (Sandberg et al. 1968). Certain prostaglandins, F1 α and F2 α , are active in the dissolution of the corpora lutea and in ovulation and these compounds cause powerful contractions of the uterus (Mackenzie 1988). Based on this information, it is possible that prostaglandins in semen are used to assist in ovulation. Other studies have shown prostaglandins to have immunosuppressive capabilities (Kelly 1995), which would assist in conception. Skibinski et al. (1992) found that that prostaglandin E1 and E2 exerted a greater immunosuppressive effect than 19-OH prostaglandin E, but considerably higher levels of 19-OH prostaglandin E in semen might contribute the majority of immunosuppressive activity *in vivo*. Thus, with the

presence of prostaglandins, immunological reactions would be inhibited for a period of time after intercourse. This may be important in embryo implantation (see below). Other suppressive agents are also present in semen and may exert specific effects (Kelly 1995). Maegawa and colleagues (2002) reported a repertoire of cytokines in seminal plasma. Each of these immunosuppressants may act in the female to temporarily lessen her immunological reaction to the foreign bodies (sperm) invading her vagina and cervix.

There are other compounds in semen that appear to play a vital role in the initiation in pregnancy. T regulatory cells are essential mediators of the maternal immune changes necessary for embryo implantation. Deficiencies in T regulatory cells are linked to unexplained infertility, miscarriage, and pre-eclampsia in women and male seminal fluid is a potent source of the T regulatory cell-inducing agents Transforming Growth Factor- β and prostaglandin E (Robertson et al. 2013). T regulatory cell-inducing cytokine Transforming growth factor and male alloantigens present in seminal fluid may be sufficient to induce a state of active immune tolerance to paternal alloantigen. This seminal fluid priming impacts fetal survival in later gestation (Robertson et al. 2009). Transforming growth factor- β and other cytokines and prostaglandins result in improved endometrial receptivity to the implanting embryo. Cytokines have embryotrophic properties and also contribute directly to the optimal development of the early embryo (Robertson 2005). Researchers continue to identify both new seminal compounds and new roles for existing compounds in female reproduction, while at the same time fertility researchers and practitioners continue to see the effects of seminal fluid in pregnancy outcomes (Robertson and Sharkey 2016).

Pregnancy Outcomes

Compounds defined by their pregnancy maintaining effects are present in semen, implying that repeated insemination after conception may play a role in producing positive pregnancy outcomes (see Davis and Gallup 2006 for review). Live birth rates in couples undergoing in vitro fertilization are

significantly improved when they engage in intercourse prior to embryo transfer (Tremellen et al. 2000) and treating women who suffer recurrent miscarriages with seminal plasma also improves pregnancy success (Coulam and Stern 1993).

Preeclampsia is a contributing factor to maternal mortality and perinatal morbidity and mortality (Klonoff-Cohen et al. 1989) and is more likely in pregnancies that occur by artificial insemination, a procedure that sometimes requires the separation of spermatozoa from the seminal fluid (Koelman et al. 2000). One of the major protective factors against preeclampsia appears to be repeated exposure to the father's semen; women who have limited exposure to the father's semen are at an elevated risk (Robertson et al. 2003) and the risk of preeclampsia is reduced by repeated (paternal) semen exposure over time (Klonoff-Cohen et al. 1989).

Conclusion

Human semen biochemistry appears to have been selected to suppress the female immune system and increase female sexual interest, bonding, the potential for orgasm, the probability of conception and pregnancy maintenance. Researchers continue to discover seminal compounds that affect ovulation, conception, and in particular, implantation and early pregnancy survival.

Definition

Observing others leads to recreational mimicry of witnessed behaviors; this mimicry (i.e., play) is a form of practice that allows children to develop a greater understanding of social norms, societal rules, and how these norms and rules influence social behavior.

Introduction

Social learning and play are of the utmost importance in the development of individuals, not only along the extent of a single lifespan but also for the development and evolution of a species. Social learning is imperative for transmitting information from one generation to the next. Play is vital for the practice and development of new methods for a species to grow and advance.

Development Through Social Learning

Social learning can be thought of as a way to transfer information, not through genetic inheritance, but rather from a learning process that comes from observing behavior of other individuals (Mesoudi and Whiten, 2004). In his early works with Social Learning Theory, Bandura (1977) stated that social learning is helpful for individuals “to acquire large, integrated patterns of behavior without having to form them gradually by tedious trial and error” (p. 12). From this, it is easy to see that children observing successful adults can learn certain societal roles and behaviors, techniques to hone specific skills, and acquire the morals adopted by the culture in which they live. Bandura et al. (1961) showed that children watching adults tended to imitate the behaviors that the adults modeled for them. In their studies, they had adults commit either violent acts or nonviolent acts. Children watching violent behavior had a tendency to act much more aggressively while the children watching

nonviolent behavior had a much stronger tendency to act in a less aggressive manner. From an evolutionary perspective, it is very beneficial for children to observe their adult counterparts to learn successful strategies to achieve a specific goal. An example of this would be a child following a hunter for food. By observing how the hunter successfully stalks and kills prey, the child can then learn how to become a successful hunter. The same could be said for farming techniques to be able to efficiently produce the greatest amount of crops possible. As for learning cultural norms, social learning comes into play with how societies view gender roles. Traditional agentic and communal gender roles are passed from generation to generation by social learning. Moral judgments about what is right and wrong can also be passed down from generation to generation via social learning. An example of this could be stealing. By observing the consequences of what happens to an individual when they break societal norms, children learn what is considered acceptable behavior and develop morals along the lines of what works best for their society.

Importance of Play

While social learning is paramount for learning specific behaviors, play is equally important for the development of these behaviors. Play is a very important resource for children. Play allows children to reenact behaviors that they have witnessed and expand on what they have seen. Bandura et al. (1961) found that after children viewed violent behavior from adults, they were more likely to generate new ways of violent behavior. While they never observed an adult use a doll as a weapon, children would make use of the doll as a tool that in a way was unintended. This shows that play allows for the creation of new ideas. Children need play to practice the behaviors that they have learned by observing adults, but also children may create a new idea that is similar, yet different than what was modeled for them. These new ideas may be more efficient or help solve a new problem. It is

easy to observe how predatory animals use play to practice hunting techniques. The same could be said for the development of survival as humans grew as a species. Developing new ways to hunt with projectile weapons made hunting a much safer endeavor. Play is essential for the development of these new techniques. Play is also crucial for practicing roles that a society deems as important. An example of this could be seen in how children play “house.” This game allows children to practice gender roles in the specific society for which they are a part. Play is also important for the practice of acceptable moral behavior. This can easily be seen in the game “cops and robbers.” Robbers are “punished” for pretend crimes once the cops catch them.

Conclusion

As we can see, social learning and play are very important for the development of children and the development of a species. One generation learns behaviors by virtue of social learning from the previous and pass what they have learned onto the next generation. Play allows for the practice of old techniques and development of new practices to help advance the species.

Tool play

Definition

Play is a pleasurable activity conducted with no apparent purpose; tool use refers to the use of different objects in the service of a goal.

Introduction

Children's play has held notable allure to child developmental psychologists and educationalists for a number of years, and since the time of Groos (1898, 1901), at least, play has been thought out as a hallmark of childhood. According to other numerous play theorists, too, such as Piaget (1962) and Vygotsky (1978), play during childhood gives the opportunity to children to learn the skills they need for a successful and healthy functioning in adulthood. This section considers different approaches in terms of defining play, explains what object play is, and finally addresses the concept of tool use in childhood.

What Is Play?

Although when we see play, we can recognize its occurrence, putting forward an operational definition has not been an easy task. Given the complexity of the phenomenon, it is universally agreed that no one definition of play is necessary or sufficient; thus definitions are usually multi-dimensional. According to the functional approach, play does not have a clear external

goal or an obvious end in itself, neither clear immediate benefits to the individual (Smith et al. 2015). In fact, a "functional" way of perceiving play is suggested – play is performed rather for its own sake and for enjoyment instead of for any other external purpose (Smith et al. 2015). Therefore, if an external goal exists such as a need to seek comfort or attention, then the behavior cannot be considered as play (Smith et al. 2015).

Similarly, the structural approach is primarily concerned with behaviors present only during play or the way these behaviors are organized during playful activities (Smith et al. 2015). These behaviors are usually called "play signals" and could, for example, take the form of laughter or the "open-mouth play face" which both signal play (Smith et al. 2015).

The two approaches, although logically different, could be considered to be theoretically in parallel and complementary to each other; after all, the child running up and down the slope has no clear, immediate goal except from enjoyment (Smith et al. 2015).

Finally, another approach suggests that play or playful behavior can be identified through a number of different criteria (Smith et al. 2015). No criterion is adequate enough to define playful behavior, but the more criteria are present, the higher the agreement will be on that a behavior is play (Smith et al. 2015). Based on this premise, Krasnor and Pepler (1980) proposed a model, which suggests that playful behaviors are characterized by a form of "flexibility," "positive affect," "nonliterality," and "intrinsic motivation."

Object Play

Jean Piaget's (1952) theory of cognitive development suggests that young children's perception and understanding of the surrounding world depend on their motor development – a fundamental skill necessary for the young child to associate visual, tactile, and motor representations of objects. Specifically, the infant has to understand that objects exist even when they cannot be seen, touched, heard, or sensed in any other way – what we call "object permanence" – and this

understanding comes through touching and handling objects in different ways (Siegler et al. 2017). Although initially this is best expressed as exploratory, as the child progresses through the sensorimotor stage, which usually lasts from birth until 2 years of age, exploratory behaviors are repeated and thus, perhaps enjoyed – two criteria for playful behavior to be present (Smith et al. 2015). These behaviors become also more flexible, such as that some of them would easily be characterized as playful (Smith et al. 2015).

As Piaget's theory further suggests, young children during their first 2 years of life are primarily focused on the activities of their own body (Siegler et al. 2017). Once their attention shifts from basic body reflexes to the events of the surrounding world, the stage is set for the appearance of object play (Hughes 2010). Except from the infant's interest in the world around them, however, there is another requirement for object play to occur: the motor skills needed to allow the infant to grasp and handle play objects (Hughes 2010).

Object play refers to playful behavior involving the use of different objects such as building blocks, jigsaw puzzles, cars, dolls, etc. (Smith and Pellegrini 2013). For instance, when babies engage in play with objects, they usually mouth objects and then they drop them down, while toddlers manipulate the objects such as assembling blocks, or sometimes they pretend play such as feeding a doll (Smith and Pellegrini 2013). Over time, young individuals learn how to use other, more abstract objects to portray other objects (Pellegrini 2016). Play with objects gives the opportunity to children to create new combinations of actions as well as to advance their problem-solving skills (Smith and Pellegrini 2013). Indeed, of all the possible uses of objects, play with objects is most highly akin to creativity (Pellegrini and Hou 2011).

In modern societies, object play typically involves toys which are made to favor children's play by being created based on mass media prototypes (Smith 2009). There is a huge production not only of simple toys and objects such as building blocks, jigsaw puzzles, cars, dolls, and toy animals but also of toys used for pretending and

fantasy activities, such as farm sets, castles, trains, action figures, and action objects based on either older but ongoing or current TV series or films such as Star Wars (Smith 2009).

As mentioned earlier, before babies, toddlers, and children engage in object play, they must explore the object first (Hutt 1966). In this initial exploration, young individuals extract characteristics of and uses for novel objects and individuals and then use this information as a basis for play bouts (Pellegrini et al. 2007). To illustrate, imagine a child entering the nursery school for the first time, being introduced to a completely new setting (Pellegrini et al. 2007). The child will allow substantial amount of time during the very first few weeks of their experience, to explore the physical and social environment of the nursery school – being a passive onlooker (Pellegrini and Goldsmith 2003). Exploration is used not only to become familiar with a new setting, but it is also needed to identify any potentially dangerous aspects of an environment and discover how to stay away from them (Spinka et al. 2001). Once a child determines that the novel environment is safe, then play can occur (Pellegrini and Goldsmith 2003).

Finally, it should be noted that any benefits of object play should be compared against those of instruction, keeping in mind different external influences such as the age of the child, the type of task, and whether learning is for particular skills or a more general developmental acquirement (Smith and Pellegrini 2013).

Tool Use

According to Bruner (1972), the design features that object play entails make it an appropriate and suitable way of developing tool-using skills. When considering the early development of tool use in infancy and childhood, the extent to which young children can indeed explore different objects' functions should be kept in mind (Deak 2014). Ideally, a common definition of "tool use" suggests that individuals make use of objects not attached to the environment or being part of individuals' bodies, in the service of a goal, for

example, getting food (Shumaker et al. 2011). To illustrate, using a fingernail to twist a screw would not be considered as an example of tool use, but using a screwdriver would (Pellegrini 2016). Tool use is an activity that encourages children's learning on how to use tools according to cultural conventions, such as using a fork (Pellegrini 2016).

Object functions depend on the physical layout and properties of objects such as their material, part configuration, and markings (Deak 2014). These object properties are related to tool use, and this is explained through the concept of *affordances* as suggested by Gibson (1982). An affordance is the extent to which an organism can interact with an object based on the object's properties (Gibson 1982). For example, to humans a cup affords containment of liquids or solids smaller than the mouth of the cup such as flour as well as tracing circles on paper (Deak 2014). Individual humans can achieve different affordances from the same object, too, of course such as a skilled player can exploit more affordances on a guitar when compared to an inexperienced person. This concept is relevant when we examine the early development of tool use, because in reality most objects or tools are designed to afford actions of adults and not of infants and young children (Deak 2014). As a result, infants must learn how to use tools and objects in a world with a setup engineered for adults (Deak 2014).

Unfortunately, infants and young children are not frequently, or sometimes not at all, allowed to explore object affordances or in other words to explore what they can do with a particular object. This is not only because of young children's physical limitations but also by the limited accessibility to these objects as adults usually design children's environments in such a way that they prohibit children's access (Deak 2014).

However, as infants grow and develop, so do their sensory and motor abilities, and these are the necessary skills needed for the development of tool use. Infants age 6–12 months old readily manipulate novel objects in order to explore their functions and properties – squeezing soft objects or banging hard objects (Bourgeois et al.

2005). As explained above, it is through exploration that children become familiar with novel objects, and once they do so, they enjoy their interaction with them. Exploration is a progressive, embodied, multimodal process that progressively allows children to adapt their reaching and refine their abilities to specific and similar novel objects, in other words, to detect new affordances (Deak 2014). Refinement can be gradual in the sense that younger infants learn how to use a type of tool, for example, a spoon, after a substantial amount of time of experience.

Further, as Tomasello (1999) suggested, tool use is supported by social interaction, with adults having an important role in children's tool-use learning. Specifically, infants and young children shift their attention to objects as a consequence of interaction or observation of adults using objects and tools (Deak 2014). For instance, when adults hold objects, children in turn become interested in those objects and reach out for them, to examine and learn about them (Tomasello 1999). Thus, it is suggested that social learning and sensorimotor development are combined in an attempt to favor tool-use learning in infants and young children.

In summary, as the young child moves from infancy to childhood, their tool-use skills are dependent on active, sensorimotor development. Through the acquisition of their sensory and motor abilities, infants and young children are able to explore novel objects and gradually learn how to use them in different ways, just like adults.

Play as Adaptation

► Evolution of Play

Play Fighting in Boys

Jason Grotuss

University of North Florida, Jacksonville,
FL, USA

Synonyms

Boys; Dominance; Physical aggression; Play;
Rough and tumble

Definition

Two or more prepubertal boys pretend as though they are fighting, without intentionally causing the harm associated with actual combat.

Introduction

Play can be very generally defined as a set of pleasurable activities, performed for the sake of the activity itself without a specific end point or goal. One category of play includes physically aggressive play fighting, in which young males participate in much more than young females, across practically every culture and mammalian species. The underlying reasons for play fighting include physiological, social, and evolutionary factors, from both ontogenetic and phylogenetic perspectives.

Definition of Play

Structurally, play is an activity marked by novel behavioral patterns that is exaggerated or discrepant, divertive, and orientated. Functionally, play has been viewed in many different ways: providing exercise and elaboration of skills needed for survival in adulthood, behaviors with immediate gratifications and no ulterior motives or benefits, and rehearsing social history by acting out instincts that characterized earlier phylogenetic evolution (Smith 2005). Play has important roles in socialization for many mammals; the more intelligent and social the species, the more elaborate the play, with humans displaying the most elaborate and differentiated types of play in the animal kingdom.

Mammals that are part of playful species begin to play as soon as they develop coordinated muscle movements. Play is most prominent during early development in most mammals, peaking during 2–9 years for wild chimpanzees, who have the most elaborate and free-ranging forms of play among nonhuman primates. Play can be separated from other early emerging behavioral activities like exploration, in which objects are manipulated to gain information, that dominate behavior for the first 9 months in humans. By 12 months, play and exploration co-occur, and by 18 months, play accounts for more of a child's interactions than exploration (Bjorklund and Pellegrini 2002). Involvement in playful activities generally follows an inverse U shaped curve, beginning and rising in infancy, peaking in the juvenile period, and fading during sexual maturation in early adolescence. In humans, however, play continues past adolescence and into adulthood, where the activity has become professionalized in many cultures.

Types of Play

Play can be broken into several categories, such as object play (involving nonfunctional manipulation of objects) or fantasy play (using mental representation of a situation as part of a

reenactment); however, play often has a vigorous physical component, which can be referred to as physical activity play, locomotor play, or exercise play. Robust sex and gender differences exist regarding physical types of play, with males participating in locomotor and exercise play to a much greater extent than females. Gross body movements observed beginning from birth, such as body rocking and feet kicking, are known as rhythmic stereotypies and have no apparent sex differences (Pellegrini and Smith 1998). By the end of the first year, however, solitary and social exercise play that involves physically vigorous gross locomotor movements, such as chasing, jumping, and climbing, begin to occur to a greater extent in boys than in girls. Exercise play peaks around 4–5 years of age, taking up approximately 20% of overall physical activity, and it occurs more often in open, spacious environments, with gender differences increasing throughout childhood to mid-adolescence (Pellegrini and Smith 1998).

Young girls not only engage in less exercise play than boys but they also report a significantly lower exercise self-schema (viewing self as less athletic), even though their social support is similar to that of boys for exercise, exercise models, exercise norms, the benefits/barriers differential, sedentary time, and access to exercise facilities and programs (Garcia et al. 1995). Exercise play begins to decline overall around 6 years of age in Western cultures, primarily due to restraints imposed by schools (Bjorklund and Pellegrini 2002).

R&T and Play Fighting

One type of physical play that males engage in to a much greater degree than females is referred to as Rough and Tumble (R&T) play, which is found in virtually all human cultures. R&T play is inherently social, as it involves either direct physical contact with others such as grappling, wrestling, holding, punching, pushing, shoving, or kicking (Smith and Boulton 1990). Additionally, R&T play can involve noncontact forms, such as

chasing or fleeing. Contact R&T looks very similar to actual fighting but has several distinct differences: it occurs in a playful context including the presence of a “play face,” does not commence with a threat, usually ends with continuing social activity between partners, often takes place between friends, and often involves self-handicapping and alternation of roles (Smith and Boulton 1990). R&T play emerges around 3 years of age and accounts for approximately 3–5% of play behavior in preschool children, 7–8% of recess behavior at ages 6–10, about 10% of activity at its peak from 7 to 11 years, and only 5% at 11–13 years at its initial decline, which is then followed by a mere 3% at 14 years (Bjorklund and Pellegrini 2002; Pellegrini and Smith 1998; Jordan 1995). During childhood, R&T is distinct from fighting, but around the adolescence period, R&T involves more cheating, manipulation, inflicting actual harm, and a focus on establishing dominance status. Late adolescence and early adulthood is the period in the lifespan where male–male competition becomes the most intense, with serious physical assaults and deadly physical aggression on the rise.

First documented in rhesus monkeys by Harlow and Harlow in 1965, R&T play occurs not just in humans but in most young mammals where it consumes approximately 10% of time and energy budgets. Participation in aggressive social encounters is also not restricted to only males. Across primate species, female-on-female physical aggression is just as common as male-on-male physical aggression; however, female aggression is less intense, less prolonged, and results in fewer injuries and fatalities than male aggression (Geary et al. 2003). In children, contact forms of R&T are more prevalent among boys, but noncontact forms tend to be similar for both genders (Geary et al. 2003). Preschool boys in the United States engage in playful physical assaults and other forms of R&T play 3–6 times more frequently than do same-age girls (Jordan 1995). Boys are also more likely to adopt goals of promoting their self-interest, controlling social situations, seeking revenge, and adopting hostile and dominance-related goals (Rose and Rudolph 2006).

Underlying Factors in Play Fighting

There are several underlying reasons for boys to engage in R&T and play fighting to a greater degree than girls. From an ontogenetic perspective, both nature and nurture exert significant pressures on males to encourage play fighting and aggression that are quite distinct from the pressures placed on females. Physiologically, the class of steroid hormones primarily responsible for the development and maintenance of male characteristics are androgens, which are produced by the testes. Androgens promote the enlargement of skeletal muscle cells, exert influences on the organization of brain circuits, change characteristics of play activities, and have regulatory effects on cognition, sexuality, emotion, and personality (Rubinow and Schmidt 1996). One clear effect of androgens observed in animal studies is increased aggression, which has been linked to testosterone in particular. For instance, adult groups selected for high levels of aggressiveness are found to have higher testosterone levels compared to control groups (Archer 1991). The relationship is bidirectional, however, between androgens and aggression. It is not just the case that testosterone influences aggression, as physical exercise and aggressive and competitive encounters also increase levels of testosterone. Both boys and girls possess androgens, but boys produce greater amounts overall; and the levels of androgens in boys dramatically increase during puberty and sexual maturation.

Socially, boys are exposed to greater social conflict and aggression compared to girls. Fathers spend more engaging in R&T play than mothers and also more time engaging sons in R&T play than daughters. In school environments, the activity of girls is more closely supervised than the activity of boys, which may have an inhibiting effect on female aggression (Bjorklund and Pellegrini 2002). Adults apply strong differential socialization pressures on boys and girls. Still, studies of children’s social preferences indicate that boys will independently seek out and interact with same-sex peers in groups more frequently than with girls, form large same-sex groups, and engage in coalitional competition once these

groups are formed (Geary et al. 2003). Both girls and boys interact with same-sex peers more frequently than opposite-sex peers throughout childhood, which results in the vast majority of children being exposed to same-sex peers far more than opposite-sex peers, leading to different relationship styles forming within same-sex peer groups than for opposite-sex peer groups. Boys from preschool to adolescence are more likely to have dense social networks and well-defined dominance hierarchies, engage in physical types of sports and games, and participate in physical contests over control of desired objects (Rose and Rudolph 2006). Additionally, boys are more likely than girls across childhood and adolescence to be victims of direct physical aggression, as well as verbal aggression or harassment by peers. In adulthood, male-on-male homicide is 30–40 times more common than female-on-female homicide (Geary et al. 2003).

Evolutionary Factors in Play Fighting

To understand why males are more physiologically and socially predisposed to play fighting and aggression, it is crucial to examine phylogenetic history for underlying evolutionary pressures on development. In most mammalian species, males invest little in parenting and much more in competition for mates, whereas females invest heavily in parenting and are the choosier sex. This pattern of male-on-male physical aggression, and associated sex differences, are expected for a species in which reproduction-related intrasexual competition has been more historically intense for one sex more than the other.

In all species of hominids, including the ancestors of modern humans, there is evidence of a male advantage in physical size, musculature, cardiovascular capacity, and bone density and architecture. The fossil record suggests at least 4 million years of evolutionary history of physical male–male competition in the human lineage (Geary et al. 2003). For males, one of the more common expressions of intrasexual competition involves one-on-one physical threats and fights for privileged access to resources and mating

opportunities. The advantage provided by aggressive play fighting in boys is to practice and hone the skills they have historically needed to acquire desired resources and sexual partners in adulthood.

One of the primary results of play fighting in boys is the establishment of a social dominance structure. Social groups are rarely structured equally, and within all human cultures there exists some form of social stratification. Dominance hierarchies created by alpha status individuals through unequal fighting ability (or inheritance) have deep evolutionary roots in many group-living animal species, including chimps, who display strong social inequality. Dominance hierarchies are prevalent (to different degrees) in modern hunter-gatherer societies, where physical dominance and skill as a warrior are related to social status among men. Play fighting can serve as an indicator of status in relationships, reaffirmation of friendships, and knowledge/establishment of the dominance hierarchy, with achievement of dominance in the peer group having both immediate and long-term effects (Geary et al. 2003). For example, longitudinal studies of children in middle school indicate that dominance-related strategies were more important for boys than girls in dating popularity with increases in dating being associated with decreases in segregation and increases in dominance (Pellegrini and Long 2003).

Conclusion

In summation, play fighting in boys is a result of increased overall physical activity and aggression in males due to various social and biological factors. There are immediate benefits to play fighting such as physical exercise and coordination, developing leadership abilities, emotional regulation (fear, aggression), greater tolerance for interpersonal conflict, self-efficacy, and opportunities for learning specific skills (Bjorklund and Pellegrini 2002; Geary et al. 2003). There are also delayed, long-term benefits for play fighting into adulthood, such as higher positions in a social hierarchy, which is directly related to access to desired

resources, preferential mates, and social dominance. It is not just in hunter-gatherer societies wherein social dominance established by physical prowess confers large benefits. In technologically developed cultures, aggressive physical competition can result in very high status in terms of professional sports and athletics.

Pleiotropy

Bryan L. Koenig
Department of Psychology, Washington
University in St. Louis, St. Louis, MO, USA

Definition

When a single gene has multiple phenotypic effects.

Introduction

The founder of genetics, Austrian friar Gregor Mendel, observed in his pea-plant experiments

that three phenotypic traits were inherited together in one of two sets: “brown seed coat, violet flowers, and axial spots or a white seed coat, white flowers, and lack of spots” (Stearns 2010, p. 767). Such strong covariation in phenotypic traits likely resulted from changes of a single gene. A single gene influencing multiple phenotypic traits is referred to as *pleiotropy*, a term introduced in 1910 by Ludwig Plate, a German geneticist (Stearns 2010). For evolutionary psychologists, pleiotropy has been especially important for the evolutionary explanation of aging and its role in human diseases and apparently fitness-reducing behaviors.

Evolutionary Theory of Aging

Medawar (1952) first suggested that pleiotropic genes could result in the evolution of senescence – increased mortality with advancing age – but he did so only in passing. In a highly influential paper, George C. Williams (1957) more fully explored this possibility. Williams developed the theory that aging evolved as a result of *antagonistic pleiotropy* – when a gene’s effects are beneficial early in life but harmful later in life. Natural selection would favor such pleiotropic genes, because the force of selection is stronger earlier in life than later in life. For example, a deleterious gene that results in death would be calamitous for fitness if expressed before reproduction, but not if expressed later in life after most lifetime reproduction has already occurred. The late-life harmful effects of various pleiotropic genes, Williams argued, would result in aging.

Molecular Genetics

The theoretical plausibility of pleiotropy assumed by Medawar and Williams has been transformed by technological advancements in molecular genetics into understanding of the mechanisms by which pleiotropy actually occurs. According to the modern theory of genetics, genes in DNA strands are read to produce mRNA, which in turn directs the production of proteins that act at the

cellular and intercellular level to affect phenotypes. Within this context, pleiotropy results when a single gene codes for a single multifunctional protein that, through one of at least seven different mechanisms, has multiple effects on the phenotype (Hodgkin 1998). Alternately, a single gene can result in the production of multiple proteins, each with different effects on the phenotype. This occurs in at least three ways (Stearns 2010). First, different proteins can be created if a gene is read by different start/stop codons, analogous to starting and stopping the reading of this sentence at the first and last word in one case or in another at the second and sixth word. Second, when mRNA is spliced to remove introns in preparation for protein production, the splicing can occur in different ways that produce different mRNA. Finally, cells can directly edit mRNA itself, changing the protein it produces.

Prevalence and Disease

Some early theorists suggested that all genes are pleiotropic, because their effects provide the context in which other genes work, but modern methods including experimental manipulations of genes suggest instead that most genes influence about four to eight traits (Stearns 2010). An analysis of data from genome-wide association studies found that about 17 % of human genes involved in diseases are pleiotropic, but this study might underestimate the prevalence of pleiotropy because it looked only for pleiotropy involving previously measured diseases and traits (Sivakumaran et al. 2011). One review identified numerous diseases whose underlying genetics result in antagonistic pleiotropy (Carter and Nguyen 2011), including the well-known example of sickle-cell anemia. This disease occurs for people who have two copies (homozygotes) of the autosomal recessive version of the gene. Their malformed red blood cells carry insufficient oxygen to the body and damage tissues. People with only one copy of the gene (heterozygotes), however, benefit from increased resistance to malaria and do not develop sickle-cell anemia.

Types of Pleiotropy Based on Effects

For people living in malaria-infested regions, the gene that causes sickle-cell anemia results in enhancement to fitness for people with one copy but a reduction in fitness for people with two copies. The gene has both beneficial and detrimental phenotypic effects and so is a type of antagonistic pleiotropy (Carter and Nguyen 2011). Evidence suggests homosexuality might also result from genes whose effects decrease fitness in some who carry them but increase fitness in other carriers (Zietsch et al. 2008). These divergent effects on fitness occur for different people, and so can be distinguished from the more commonly considered kind of antagonistic pleiotropy conceived by Williams (1957) in his theory of aging wherein the early life benefits and late-life costs were within-person. A prominent example of this is that higher levels of testosterone reduce longevity but increases mating success in human and nonhuman males (Hau 2007). Other distinctions among types of pleiotropic effects have also been proposed. Hamilton (1966) pointed out that “all genes which are age-specific in their action are pleiotropic, simply by the fact that they cause positive effects at some ages and null ones at others” (p. 35). This might be called *late-onset pleiotropy*. Rose and colleagues (Rose et al. 2007) noted that, “Morphological size characters often show ‘positive’ pleiotropy, whereby alleles that increase the size of one limb, for example, also tend to increase the size of other body parts” (italics added, p. 1267). Thus types of pleiotropy can be distinguished based on whether the multiple effects occur within an individual or between people and the fitness consequences of the effects: antagonistic, null-then-positive, or all positive. Pleiotropy can also be distinguished based on different molecular genetics mechanisms as described above.

Conclusion

The concept of antagonistic pleiotropy has played a large role in the evolutionary theory of aging. Modern molecular genetics research has substantially illuminated many of the mechanisms by

which pleiotropy can occur and demonstrated that it is fairly common. Pleiotropy can have opposing effects on fitness, consistent effects on fitness, or late-onset effects. The effects of pleiotropy can appear within a single individual or across individuals. Diseases and psychological traits that seem to reduce fitness are sometimes explained as resulting from selection pressure on the pleiotropic effects of related genes.

Synonyms

[Political ideology](#); [Political orientation](#)

Definition

Where an individual falls on the political spectrum, usually a left-right continuum, which strongly determines their voting preferences.

Introduction

Political affiliation is where a person falls on the political spectrum, usually to the left or the right (Conover and Feldman 1981; Jost 2006). The right-wing and left-wing are usually defined along two spectrums: acceptance of inequality and favoritism toward the status quo (Jost et al. 2003). That is, in the first case, a preference or at least tolerance of some kind of societal injustice, either because it is inevitable or even preferable. In the second case, this means the extent to which someone prefers changing the current societal state of affairs versus changing society. Where someone falls on these two spectra will determine their political affiliation. If they prefer or tolerate inequality, they will tend to be more conservative; if they would like to assuage inequality, they will be more liberal. If they prefer to keep society the way it is or the way it has been, they will be more

conservative, whereas if they favor changing society, they will be more liberal.

What Is Evolutionary Political Psychology?

Evolutionary political psychology is the study of why political behaviors were beneficial in humanity's distant past. What made politics a beneficial adaptation? What advantages did politics give some groups of humans over others? How do these evolved adaptations continue to affect political behavior in the present day? And most importantly to the current discussion, what evolutionarily relevant variables influence people's political affiliation up to the present time? These are the kind of questions that this relatively young field tries to answer.

A helpful beginning point in explaining the evolutionary origins of political affiliation would be to decide what exactly politics is, at least in the context of humans' evolutionary past as hunter gatherers. According to Petersen (2015), politics probably developed as a way to coordinate the selfish desires of individuals in a group with the need to cooperate in order to survive. That is, each individual in the group would have wanted to maximize his or her own individual level of fitness; however, this sometimes conflicted with the fitness of the group as a whole. Thus, when an individual took down a great animal that they might have used for food, this was not political in and of itself. It became political when another individual or individuals claimed that they were entitled to a part of the food that the first individual had just acquired. It would have been in that first individual's best interest – the one who made the kill – to hold onto all of the meat they had just caught. But if they were a part of a group, those other individuals at least theoretically had a claim to some of it, because it was (and still is) generally accepted that one shares with one's ingroup members. This often put what was in the individual's best interests in conflict with what was in the group's best interest. Accordingly, a person's political preferences – policy preferences, political affiliation, etc. – would have been driven by the desire to have the group conduct its affairs in

such a way that promotes his or her best interest, as the individual himself or herself saw it. A person's perceptions, further, were determined by a number of measurable variables with evolutionary overtones (described below; e.g., Haidt and Graham 2009; Hirsch, DeYoung, Xu, & Peterson 2010). This is the case with modern political preferences as well.

Alford and Hibbing (2004) posited a similar hypothesis, but with some additions. They put forth the weary cooperator theory of politics. Similarly to Petersen (2015), they begin with the premise that humans are driven by a trade-off between the desire to act in their own self-interest and the desire to cooperate. Cooperation has clear survival benefits, but at the same time evolution should drive individuals to act in their own self-interest. Humans, being smart enough to realize that they must deal with this trade-off, therefore engage in altruistic punishment or sacrificing some potential gain for oneself for the sake of others in order to foster cooperation so that they can benefit from the protection of being in a group. However, they will also harshly punish those who do not reciprocate this cooperation, mainly because they themselves are making some sacrifice and do not like feeling as though others in their group are not doing likewise (e.g., Yamagishi and Kiyonari 2000).

Someone will make a sacrifice for the sake of the group insofar as they stand to gain from that sacrifice, and they will punish those ingroup members who do not reciprocate that sacrifice in some way, whether it be by stealing, not sharing, or committing a crime. Thus, the abovementioned individual who has just made a great kill will willingly give up some of the meat from their kill, because they know that doing so ensures their place in a group, which helps to promote their survival. This trade-off between altruistic punishment (i.e., willingly sharing with others) and selfishness, plus the desire to see those who do not reciprocate altruistic punishment, drives much of political behavior, according to Alford and Hibbing (2004). Thus, according to Alford and Hibbing, evolutionarily driven political behavior is not always entirely selfish, which stands in contrast to Petersen (2015).

Thus, a person's political preferences will be driven in part by their desire to promote their own best self-interest. If they see more liberal policies as being beneficial to them, then in the United States they are more likely to be a Democrat. If they see more conservative policies as being beneficial to them, then in the United States, they are more likely to be a Republican (but see Weeden and Kurzban 2016, for a counter-argument). But they also willingly make sacrifices of their self-interest to a degree for the sake of the group. This explains liberal individuals' willingness to invest in welfare programs – which often do not benefit them directly – and conservative individuals' willingness to sacrifice safety nets in order to promote spending on the military – which also does not tend to benefit them directly. In summary, there should be a number of evolutionarily driven variables – especially reproductive strategies (see below) – that predict whether someone will fall on the left or right of the political spectrum.

Evolutionary Predictors of Political Affiliation

What evolutionarily relevant variables predict political affiliation? This is a relatively new area of study, but some preliminary results suggest that evolutionary variables affect people's political affiliation. For example, Pinsof and Haselton (2016) found that participants with more of a short-term mating orientation (STMO) – meaning mating habits that require little investment over a long period (e.g., being promiscuous) – were more accepting of gays and lesbians, and that this was mediated by perceptions that gays and lesbians were promiscuous. That is, those who showed greater favorability for a long-term mating orientation (LTMO) perceived gays and lesbians as more promiscuous, and this accounted in large part for why they had negative attitudes toward homosexuals (also see Pinsof and Haselton 2017), attitudes that have obvious implications for political affiliation in the United States and many other countries. Those who have a LTMO will be more likely to be conservative, while those with a STMO will be more likely to be liberal.

Something similar has been found with regard to people's attitudes about recreational drugs, another issue with great implications for political affiliation in the United States. Kurzban et al. (2010) found that people with more of a LTMO showed more negative attitudes toward recreational drug use that remained significant even while controlling for political affiliation. This, they argue, is because people who use recreational drugs are perceived as more sexually promiscuous (i.e., have more of a STMO), because recreational drug use and promiscuity tend to be correlated (e.g., Whitaker et al. 2000). Thus, attitudes toward recreational drugs and homosexuals – which tend to be more negative among conservatives, who often oppose the legalization of drugs like marijuana, and tend to be more positive among liberals, who support the legalization of drugs like marijuana – are determined, at least in part, by mating orientation, a variable with heavy evolutionary overtones (Kaplan and Gangestad 2005).

Petersen (2012) also investigated a possible evolutionary origin of people's attitudes toward welfare. He performed a study on the deservingness heuristic. According to the deservingness heuristic, other members of one's ingroup who are perceived as cheaters (free-loaders, those who are not doing their part to support the group) will be perceived as undeserving of help, and those who are perceived as reciprocators (working or at least doing their best to help the group) are perceived as deserving of help. In theory, the deservingness heuristic is out-of-date in modern nation-states, which are much vaster than the hunter-gatherer bands in which humans evolved. However, the time from humans' hunter-gatherer past to the present was not long enough for humans to evolve new psychological mechanisms for judging the deservingness of others. Thus, it still influences the way people judge the extent to which welfare recipients are deserving of the assistance they receive. To that effect, Petersen ran a study where he found that participants tended to view people receiving help (whether it was welfare or help from a friend) and not putting effort into finding a job as cheaters in the sense of cheaters from humanity's hunter-gatherer days. Those who were being helped (whether it was welfare or help

from a friend) who were putting in effort were perceived as reciprocators. On the other hand, when no information was given about the effort they were putting in, the participants did not make this distinction. Thus, a deservingness heuristic that evolved to function in small bands of hunter-gatherers – in humanity's evolutionary past – continues to cause people's political attitudes today. When someone is perceived as a cheater, they will be perceived as undeserving of welfare assistance.

Interestingly, Petersen (2012) did not find that these effects were moderated by political affiliation. This would seem to be evidence contrary to the above contention that individual differences on variables such as the deservingness heuristic determine political affiliation. However, there is a possible counter argument to this, although it has yet to be explicitly tested. Skitka et al. (2002) put forth the motivated correction hypothesis of political affiliation. According to this, liberals and conservatives (this research was done in the United States) probably make similar attributions as to why poor people are poor, why criminals commit crimes, and other attributions important for determining political affiliation – but while they make the same attributions (e.g., poor people are poor because they are lazy; criminals commit crimes because they are horrible people) when they are made under cognitive load or under time pressure, when they are given more time to think about their views, liberals tend to change their attributions from the initial gut reaction (poor person is poor because he's lazy) to a view that is more in line with their ideology (poor person is poor because of economic inequality). Conservatives do not do this, because their immediate reaction tends to be more in line their ideology. It is possible that these effects would occur if cognitive load or time pressure were investigated as mediators in Petersen's (2012) study.

Moral Foundations and Motivated Social Cognition

Two further theories with evolutionary relevance have posited variables that predict political affiliation. According to the theory of political

conservatism as motivated social cognition (PCAMSC), political conservatism is heavily correlated with a number of epistemic (e.g., need for cognitive closure) and existential variables (e.g., fear of death; Jost et al. 2003). In this model, the need to perceive the world as simple, predictable, and knowable and the desire to see the world as meaningful are highly predictive of political conservatism (cf. Skitka et al. 2002). Indeed, they found support for this in an extensive meta-analysis of studies predicting political conservatism, finding variables such as fear of death, mortality salience, need for cognitive closure, need for cognition, and need for order across 88 different samples – and research since then has corroborated their findings (Jost and Amodio 2012).

Somewhat relatedly, Haidt and Graham (2009) put forth moral foundations theory (MFT). In their model, there are five moral foundations that were the basis for making decisions about what is right and what is wrong (i.e., shorthand for making moral decisions) in humanity's evolutionary past. They evolved according to natural selection because they helped humans in the evolutionary past to survive and pass on their genes more effectively. Different cultures at different times valued different foundations more or less than others, but each of them plays some part in every human culture, according to the authors. The five foundations are harm/care, to keep oneself safe and help others avoid being hurt and to relieve pain; fairness/reciprocity, help those who are good and harm those who are bad; ingroup/loyalty, need to belong to groups and punish traitors to the group; authority/respect, accord those of higher standing in the social order the respect they deserve (including, at times, obedience); and purity/sanctity, avoid being contaminated by dirty or immoral objects or people.

The harm/care and fairness/reciprocity foundations are categorized as individualizing foundations, because they place emphasis on the welfare of individuals. The other three, ingroup/loyalty, authority/respect, and purity/sanctity, are referred to as binding foundations, because they place more emphasis on loyalty, duty, and self-control in service of a group (Graham et al. 2009). Survey research measuring the five moral foundations has shown that liberals tend to rely on the

individualizing foundations, whereas conservatives tend to rely on all five (Haidt and Graham 2009).

Conclusion

Political affiliation, then, results from some combination of which moral foundations they value, where they fall on epistemic and existential variables, and other individual differences regarding mating strategy and their application of the deservingness heuristic. Future research is clearly needed, but this is where the field stands. It would seem that political affiliation – and by extension, political parties – evolved as a way for humans to serve their self-interest while maintaining the integrity of the group. Those who hope for a world where everyone gets married to their one true love and work together to raise happy children will *tend* to show homonegativity and to oppose recreational drug legalization. Those who are open to new experiences and open to ambiguity will tend to favor more racial, ethnic, religious, and sexual inclusion and so on. Political parties may be so ubiquitous across political systems because they helped people with differing temperaments and desires to have an outlet through which to try and further what they saw as best for the group they lived in while also promoting their own best interests.

Definition

The Political Left describes an orientation on the liberal-conservative/left-right political spectrum that describes individuals who tend to have greater concern for promoting social equality and protecting individual liberties and who are more likely to seek political reform as compared to political conservatives.

Introduction

Although political views are complex, the utility of a single continuum that ranges from liberal to conservative, or left to right, has been demonstrated to accurately predict individuals' voting behavior and opinions on a variety of issues (Jost 2003). People who fall more toward the left end of the spectrum, often colloquially referred to as *liberals*, are more likely to defend individual liberties from authorities, traditions, and institutions (Sowell 2002); express moral concerns about fairness/equality (Graham et al. 2009); and seek political reform as compared to political *conservatives* on the opposite end of the continuum (McCrae 1996). Conservatives, who prefer familiarity, stability, and predictability (McCrae 1996), have different perspectives about moral principles and behaviors compared to liberals. Conservatives are more inclined to endorse the view that moral values are objective and universal (i.e., notions of "right" and "wrong" do not and should not vary across cultures) and that behaviors are morally acceptable if they conform to these absolutes (e.g., Van Kenhove et al. 2001). In contrast, liberals are more likely to support *moral/ethical relativism*, or the related philosophy of *cultural relativism*, which holds that moral values are valid in different cultures and societies and are all equally deserving of tolerance and respect (e.g., Graham et al. 2009; Hunter 1991; Layman 2001). Liberals have historically supported policies based on this perspective (Layman 2001).

Relativism Versus Human Rights

The philosophy of cultural relativism rose to prominence in the twentieth-century by the

advancement of American anthropologists in opposition to Western imperialism, racism, and ethnocentrism (Lukes 2008). These left-leaning anthropologists were politically active both in their own country and abroad in their quest to promote tolerance of other societies' ways of life and cultural practices. Notably, the executive board of the American Anthropological Association issued a statement to the United Nations (UN) Commission on Human Rights in 1947 urging them to implement a relativist perspective in their forthcoming Universal Declaration of Human Rights (see Lukes 2008). Although the motion failed, it sparked a worldwide debate about human rights lasting decades. This debate, often framed as universal human rights vs. relativism, continues to influence the political tendencies of individuals today as evidenced by liberals' preference for policies that counter cultural imperialism and emphasize tolerance (Lukes 2008). Perhaps the most widely discussed and contentious issue from these discussions is the practice of female genital mutilation, which some argue is a violation of individuals' fundamental human rights (Danial 2013). This position has been criticized by others who believe such a stance is congruent with Western imperialism and argue that outlawing the practice represents a morally unjustified imposition on another culture (e.g., Shweder 2000).

Conclusion

In conclusion, efforts by the intellectual left (i.e., politically liberal academic social scientists) in opposition to Western imperialism gave rise to the philosophies of moral/ethical and cultural relativism (Danial 2013). This position is frequently expressed by political liberals, who are more likely than conservatives to hold that "right" and "wrong" are subjective and specific to cultural and religious contexts (Van Kenhove et al. 2001).

Definition

Politics involve the interpersonal negotiation among members of a group for power within a status hierarchy. Politics are involved in science in at least two ways. Evolutionary psychologists study the mechanisms involved in political behavior, and are subject to their own political biases which they bring to their work, which shapes both, the questions they ask and the inferences they make.

Introduction

Politics play multiple roles in science. First, as a field interested in human behavior, psychology as a field, including evolutionary psychology, has explored the mechanisms underlying variation in political ideologies. Second, like any community, the scientific community has its own norms and mores which are shaped by the prevailing zeitgeist of the cultures from which scientists come. Therefore, not only are the processes underlying variation in political ideologies studied by evolutionary psychologists and traditional psychologists, alike, but the field is often subject to the political biases of its members. In what follows, we will briefly explore

some of what evolutionary psychology has contributed to the study of political behavior and discuss the influence political ideologies have on field.

Psychological Mechanisms Involved in Political Ideologies

The approach to understanding human nature used in evolutionary psychology has contributed profoundly to the field of psychology, and the study of political ideologies is no exception. Here we will discuss several psychological mechanisms that have been used to understand variations in political ideologies. We will discuss the role of the pathogen aversion psychological mechanism in political ideology. Next, we will then discuss other psychological mechanisms proposed by Moral Foundations Theory. We begin, however, by discussing operational definitions of what it means to be conservative and liberal.

Being conservative versus being liberal has meant, and continues to mean, many things to many people. However, one distinction that has been made between conservatives and liberals is that concerning beliefs about individual liberties (Graham et al. 2013). Classic liberalism can be thought of as a belief system or set of values built on the fundamental belief that people are inherently good and benefit from greater liberty (i.e., liberal). This includes liberty from their groups and the expectations of those groups. Conservatism, on the other hand, can be thought of as a belief system or set of values built on the belief that assumes that people are not inherently good and benefit from greater restraint, whether that restraint be imposed by law or normative custom. Further, conservatism and liberalism are best thought of as existing along a continuum rather than as categorical distinctions. With these definitions in mind we now turn to the psychological mechanisms thought to produce variance in people's political ideologies.

Pathogen Aversion

Pathogens have historically presented, and continue to present, people with a selection pressure,

such that those best able to overcome disease survive longer. Certainly, our immune system plays a large role in meeting this demand. However, avoiding potential infectious agents and environments may be a preventative measure (Schaller 2006). Therefore, a pathogen avoidance mechanism that responds to inputs such as cues of potential high exposure to pathogens and parasites with outputs (e.g., the emotional response of disgust) that encourage people to avoid potentially infectious others would serve to stop infections before they even began. Schaller has proposed such a mechanism, with several other functionally similar mechanisms, in his behavioral immune system.

Researchers have argued that the psychological mechanisms that comprise the behavioral immune system can create differences in political ideologies. Specifically, research examining the behavioral immune system of political conservatives suggests that conservatives are more sensitive to disgust triggered by pathogens sexual acts and moral issues relevant to pathogen exposure and sexual acts (Tybur et al. 2013).

Moral Modules

Haidt and colleagues (Graham et al. 2013; Haidt 2012) have proposed that a suite of psychological mechanisms that process morally relevant issues is partially responsible for differences in political ideology. Namely, Haidt argues that conservatives and liberals differ in the extent to which they endorse five foundations of moral consideration and respond to cues of violations of these foundations with negative moral judgment. Haidt has organized these foundations into those that operate to benefit individuals (i.e., individuating foundations) and those that operate to benefit the groups people belong to (i.e., binding foundations). The individuating foundations include concerns with harm/care and fairness/reciprocity, while the binding foundations include concerns with loyalty/betrayal, authority/subversion, and purity/sanctity. Haidt and colleagues have suggested and found that conservatives endorse all five foundations equally, while liberals

principally endorse only the individuating foundations. It is for these reasons that conservative ideologies are thought to reflect concerns with disloyalty, subversion of authority and norms, and physical, sexual, and moral purity more so than are liberal ideologies. While liberal ideologies are thought to only reflect concern for preventing harm and ensuring fairness.

Haidt (2012) has further suggested a sixth foundation of moral concern, which he refers to as the liberty/oppression foundation. This foundation reflects a concern with the power wielded by governing individuals or entities. Specifically, those who endorse this foundation prefer weaker governing entities and greater individual liberties. Although, not much research has explored how this foundation might account for differences in political ideologies, what has been done suggests that liberals endorse this foundation more so than do conservatives (Hofmann et al. 2014).

Finally, research has begun to explore how these moral judgment mechanisms might explain libertarian ideologies. The limited work that has been done suggests that libertarians endorse the liberty/oppression foundation, but endorse all other foundations less than do liberals or conservatives (Iyer et al. 2010).

Thus far we have discussed some of the mechanisms thought to underlie variation in political ideologies. By no means have we provided or attempted to provide an exhaustive list. However, we now turn to the other important role politics plays in science, political bias.

Political Bias in Science

One of the defining qualities of the scientific endeavor is striving for objectivity. However, this is not always as easily done, as it is said. Recent commentaries and research have explored political bias in the field of psychology (Haidt 2011). Specifically, this work has revealed a strong liberal bias not only in psychology but in science in general (Honeycutt and Freberg 2017). This implicit bias is blatant when taking a bird's eye view at research examining variations in political ideologies.

While we will not provide a detailed discussion here, as such can be found elsewhere (Duarte et al. 2015), suffice it to say that a cursory glance at research examining variation in political ideologies may give the impression that the field of psychology views those with conservative ideologies negatively. Sadly, work suggests that psychologists with conservative ideologies feel as if their field views them negatively (Honeycutt and Freberg 2017; Inbar and Lammers 2012). Therefore, this suggests we must redouble our efforts to address our research questions with objectivity, putting our personal biases, political or otherwise, aside.

Conclusion

Here we have examined at least two of the roles, politics play in evolutionary psychology, a topic that has garnered great interest, and a biasing factor within the scientific community. It is ironic that those who study variations in these ideologies would be so led about by the biasing influences of these ideologies. However, given how interrelated these are, hopefully further exploration will lead our field to potential solutions.

Definition

Polyandry is the practice of having more than one husband or male mate simultaneously. It is among the rarest of human mating systems. Only 1.1 %

of cultures studied worldwide engage in polyandry.

Introduction

Polyandry has long puzzled the scholars who study it, particularly male scholars, according to Hrdy's comprehensive (1986) consideration of studies of human and nonhuman instances of this mating strategy. Its existence challenges many assumptions about human sexual and marital relationships and challenges evolutionary thinkers because of the assumption that it dramatically limits male reproductive success. Indeed when compared with polygyny and monogamy, it is relatively uncommon among humans and nonhuman primates. Demographically, among humans its most common form is fraternal polyandry, found almost exclusively among Tibetans and ethnic Tibetans of Nepal and India. Other mostly ephemeral instances of polyandry have been observed among egalitarian and primarily foraging peoples encountered in such diverse regions as the northern latitudes including among the Inuit, among some Plains tribes in North America, among some foraging populations of South America, in the Marquesas, and among the Nayar in Southern India. Aside from the Nayar, those forms of polyandry seen outside of the Tibetan culture area have typically been described as opportunistic and most likely to occur in instances of scarcity in environments characterized by patchy or temporally variable resource availability (Starkweather and Hames 2012 provide an excellent review). Among ethnic Tibetans, by contrast, polyandry is not ephemeral nor is it a temporary response to difficult environmental or economic circumstances. By contrast, it is the normative and most highly regarded marital form and typifies households considered by community members to be culturally successful.

Human evolutionary ecologists and other evolutionary thinkers use the theoretical and methodological tools from the nonhuman literature to understand human mating behavior, including polyandry. Studies from this perspective are important because they help precisely identify

the decision rules that people use in different cultural and environmental contexts as they make evolutionarily significant decisions. For instance, a number of studies have shown a positive association between a male's access to resources in various forms and their desirability to females. Others have identified the connections between female characteristics and their desirability to men as brides or mates. Studies of this kind illustrate the attention that human behavioral ecologists have focused on mate choice and on identifying and analyzing those characteristics which are most likely to ensure that a male or a female will be chosen as a mate. Our understanding of polyandry, particularly among fraternally polyandrous ethnic Tibetans, has been greatly enhanced by this theoretical lens.

Explanations for Polyandry

A primary focus of human evolutionary ecology research on polyandry has been on the timing and circumstances of marital events and the context in which they are made. Human behavioral ecological research into these questions seeks to identify the specific constraints that limit and shape marital decisions. Typically, the constraints that have been investigated by human behavioral ecologists have been factors like wealth or prior reproduction or marital histories.

This focus allows human behavioral ecologists to identify how marital decisions are affected, for instance, by economic conditions or opportunities, position in the sibling set and number of siblings, and prior marital and fertility histories. These factors have been shown to be influential in societies in which a mix of polygyny and monogamy prevails (Borgerhoff Mulder 1988; Strassman and Clarke 1996). Analyses of these issues by human behavioral ecologists rely heavily upon models borrowed from the nonhuman literature. The nonhuman models that examine flexible behavioral responses to environmental variability in nonhuman species are useful building blocks for predicting the organization of human social systems, including marriage systems, across environmental contexts. Like

analysts of mating systems in nonhumans, and based on evolutionary theory, behavioral ecologists predict that human beings will, on average, behave in ways that maximize fitness relative to other individuals in the population. Studies of mating systems across species typically test this prediction, looking at intraspecific variation in fitness as associated with mating strategy (Emlen and Oring 1977; Davies 1992; Searcy and Yasukawa 1989; Ryan and Causey 1989; Dunbar et al. 1990; Bradbury and Vehrencamp 1977).

The starting point for human behavioral ecology studies of polyandry was Emlen and Oring's seminal paper in which they argued that mating strategy will be influenced by the spatial distribution of resources and the temporal availability of mates (1977). In the same year Bradbury and Vehrencamp argued that parental care patterns also strongly influence mating systems (1977), and later studies showed that alternative mating strategies were affected by a number of other factors, for example, different strategies may be pursued by males and females depending upon age and current mating opportunities (e.g., Byers and Kitchen 1988 and Dunbar et al. 1990). The strengths of these studies lie mainly in their clarification of the importance of factors like age or position in the sibling set, as among communal breeders, as well as environmental factors such as the availability of the limiting sex (as among dunnocks after a harsh winter, when the sex ratio rose and polyandry became more common, [e.g., Davies 1991]), the availability of resources, and the importance of parental care (e.g., Beissinger 1987). Perhaps the most important conclusion to be drawn from these studies is that populations and even individuals rarely pursue the same mating strategy at all times. Populations are unlikely to be uniformly "polygynous" or "polyandrous," since individuals within a population may frequently shift from one mating strategy to the next depending on the factors listed above (e.g., Davies 1991).

The empirical studies inspired by the original models of Emlen and Oring and Bradbury and Vehrencamp have over the decades added considerable complexity to the way in which human behavioral ecologists think about marriage

strategies, including polyandry. Uniformly, individuals are regarded as active decision-makers facing specified costs and benefits and are assumed to be able to either consciously assess those or use advantageous “cultural” rules of thumb. Understanding marital strategies in polyandrous humans simply in terms of optimality or by using a small number of independent variables oversimplified the complex processes at play in these systems. Early studies suggested that polyandry resulted from a male-biased sex ratio – there were simply not enough women to go around – or suggested that polyandry was a response simply to resource scarcity. But neither of those hypotheses fit the ethnographic, demographic, and ecological realities in cultures where classical fraternal polyandry exists. Fortunately, a number of human behavioral ecological studies have taken a multidimensional approach to analyzing polyandrous systems, and these have shed light on the complexity and strategic considerations of decision-makers in these societies.

When Polyandrous Marriages Persist: A Multidimensional Conundrum

In a fraternally polyandrous society such as among ethnic Tibetans of Nepal and India, sets of brothers typically begin their marital trajectories polyandrously. Yet these systems show considerable flexibility, and communities often contain households comprised of polyandrous marriages, others with monogamous marriages, and much more rarely, households with polygynous or polygynandrous marriage. Individuals can phase out of the initial polyandrous phase of a marriage between brothers and their shared wife if and when members agree. So the question of interest has focused on those households in which polyandrous marriages persist, in comparison with those households in which polyandrous marriages partition.

Studies have shown that in a polyandrous system, the decision to stay or to leave the wife of one’s polyandrous brothers and marry monogamously cannot be simply understood, in terms of some of the variables traditionally studied by

human behavioral ecologists, like wealth or (prior or expected) reproduction. Decisions about first wives are typically made by the eldest brother together with his male kin and depend upon his age and the age of his parents, the number of brothers he has, the economic status of his fathers’ estate, his education, recommendations of local monastic authorities, and other factors related to the family system and the household economy. Similarly, the decision to partition a polyandrous marriage will depend upon age, number of children already produced, anticipated inheritance, familial monastic obligations, community sentiment, and other factors. A number of studies have shown that considering each of these factors allows a complete analysis of the strategies pursued and how individuals decide among them.

Durham’s (1991) synthesis of the competing hypotheses and evidence regarding the existence and maintenance of fraternal polyandry shows solid evidence from the earliest studies from Fischer (1952), von Fürer-Haimendorf (1975), Aziz (1978), Levine (1988), and Crook and Crook (1988), for what he termed the domestic economy theory of polyandry. These important early studies produced abundant ethnographic, economic, and demographic evidence supporting two hypotheses, including:

- a. The conservation of family property – the monomartial principle (one marriage per generation) kept estates together given the preference for and practice of partible patrilineal inheritance. In cases of partition, a per capita (male) inheritance rule would divide estates among separately marrying sons. Together, these principles serve to conserve family property across generations.
- b. The optimization of family labor – local ecological conditions set incentives for a diversified family economy, the consequence of which was an acute demand for labor and a domestic unit ratio that favored producers over dependents.

Human behavioral ecologists elaborate upon the findings from these classical studies.

Household wealth, or access to resources seemed particularly important, since most fraternally polyandrous people reside in harsh or unforgiving climates and/or topography and because wealth has been shown to predict marital decisions and reproductive success in many societies around the world. Among ethnic Tibetans practicing polyandry, it is very common for households to engage in a variety subsistence strategies, including agriculture, long distance pedestrian trade, and pastoralism. Levine and Silk (1997) showed the powerful effect of the size of the brother set and prior marital history on marriage decisions and reproductive success, where larger brother sets were less stable and the decision to partition a polyandrous marriage dramatically reduced reproductive success of active partitioners. Low socioeconomic status, long thought to be associated with the decision to marry and remain married polyandrously, did not in fact appear to be associated with the stability of polyandry among the Nyinba of northwest Nepal. But Haddix (2001) showed in her study of Panchapalli ethnic Tibetans in northern Humla District of Nepal that when the diversity of wealth holdings was analyzed, those families in households with higher economic diversity were more likely to remain polyandrous than those that were not economically diversified and for brothers to have higher reproductive success in comparison with men who opted to partition a marriage. Smith's (1998) meta-analysis established that in the most data-rich studies of polyandry that we have, even after considering the reduced coefficient of relatedness of brothers produced from a polyandrous marriage, polyandry conferred higher reproductive success upon men in certain economic circumstances and could be considered an evolutionarily adaptive response to those circumstances.

Conclusion

Polyandry represents a fascinating example of human mating strategy plasticity, and in its classical form among fraternally polyandrous ethnic Tibetans, it is a standout among marriage systems in terms of flexibility and community members'

acceptance of difference. The work of evolutionary thinkers has shed invaluable light by bringing analytical complexity to this fascinating topic.

Definition

A mating system in which one male mates with multiple females, or one female mates with multiple males, or both males and females have multiple mates.

Polygamy and Parental Investment

The concept of polygamy is at the heart of the study of mating system evolution. How many mates an individual has is likely to have a large effect on the reproductive contribution that individuals make to the next generation. However, there is an important difference between males and females with respect to polygamy that is related to the definitional distinction between the sexes (Trivers 1972). Females are defined by their production of large, nutrient rich gametes (eggs), whereas males are defined by the production of tiny, abundant gametes (sperm). The result of this dichotomy is that males in many species can profit reproductively from mating with multiple females. Developing ideas initially explored by Bateman (1948) and Williams (1966), Trivers (1972) argued convincingly that it is actually the difference in relative parental investment in offspring that is the key determinant of “sex roles,” with the sex that provides more parental investment in offspring becoming a “limiting resource” for which members of the opposite sex compete. Trivers (1972) also argued that the initial disparity in investment that defines males and females creates a bias in investment (gamete size disparity) that drives a bias in the tendency of females (as opposed to males) to invest in parental care.

This proposal met with considerable skepticism, leading to a long series of debates in the literature that are beyond the scope of this entry. However, Queller (1997) developed several theoretical arguments that supported two of Trivers’ main points concerning the influence of pre-existing investment disparities and stronger sexual selection on males on the probability of the evolution of male (as opposed to female) parental care. First, males that are likely to succeed in intrasexual competition for mates are selected to

invest in mating effort rather than parental care, and males that are not successful are rarely in a position to provide parental care to their own offspring. This does create a barrier to the evolution of male parental care. Second, differences in certainty of parentage between the sexes should strongly select against further investment by the sex experiencing lower certainty of paternity (typically males).

Although there have been some modifications to Trivers' (1972) original arguments, this seminal article developed several principles that remain cornerstones of sexual selection and mating systems theory (Kokko and Jennions 2008). Hence, in majority of animals that have been studied, males appear to be more inclined to aggressively compete for access to females. Trivers (1972) also argued that females should tend toward high selectivity in the context of mate choice. A vast literature confirms that this is typically the case (e.g., Andersson 1994). However, it does not necessarily follow that females will always avoid polyandry. In fact, with advent of the widespread use of molecular markers, it has become apparent that polyandry is relatively common in the animal kingdom. Even species with putatively monogamous mating systems were found to have frequent extra-pair copulation.

Environmental Influences on Mating Systems

The factors influencing the levels of polygamy in natural populations have been a focus of theoretical work for many years in the field of behavioral ecology. In fact, this area of study forms the main basis of mating systems theory (it is worth pointing out here that mating systems theory focused on social relationships, and did not necessarily accurately describe genetic relatedness to offspring). An early influential paper in this field was published by Emlen and Oring (1977). They focused on characterizing mating systems in terms of specific aspects of the environment and stressed the importance of environmental effects on the ability to acquire and maintain access to mates. Emlen and Oring (1977) incorporated the basic tenets of sexual selection theory

developed by Trivers (1972) into their arguments, and so focused on male access to females as mates (although they also considered sex-role reversed systems). In some cases, this would involve controlling access resources critical to females, whereas in others it would involve direct control of access to females.

They particularly emphasized the importance of spatial and temporal patterns of the dispersion of females in response to environmental heterogeneity. For example, if resources critical to females (e.g., food) are evenly and widely dispersed in patches that are not large enough to support more than a single female, then the best option for a male may be to defend access to an individual female. Conversely, if resources are distributed in patches, and each patch is enough to support several females, then males may be able to defend and mate with multiple females, resulting in polygyny (male polygamy). In the case of temporal variation, if females are ready and willing to mate (e.g., in estrus in mammals) in a staggered fashion, so that not all females in a group or area are receptive at once, then this provides the opportunity for sequential monopolization of mates by males (resulting in increasing levels of polygyny). Emlen and Oring (1977) developed several influential metrics that have commonly been used to describe mating systems, including the "Environmental Potential for Polygamy" or EPP, and the "Operational Sex Ratio," or OSR. The EPP refers to a combination of factors (e.g., the spatial distribution of crucial resources) that influence to what degree a small proportion of males in the local population (or females in sex-role reversed systems) are able to monopolize a large proportion of receptive females. Later this would be referred to as "reproductive skew" (see below). The OSR has been used as a measure of the intensity of sexual selection, although this has been controversial and a variety of other metrics have been developed (see, for example, Klug et al. 2010).

Mammalian Mating Systems

Following on Emlen and Oring (1977), a number of researchers tried to apply their logic to specific

taxonomic groups. Perhaps one of the most successful attempts in this regard was the application of these ideas to mammalian systems. Mammals have a long internal gestation, which means that beyond egg size differences, gestation time and effort impose an even higher disparity in initial male and female investment in offspring. This is probably responsible for the observation that very few mammals show paternal care. Because of this, classifications of mammalian mating systems have focused on different factors affecting polygyny. Clutton-Brock (1989) presented a classic classification of mammalian mating systems, in which he emphasized the extent to which female reproductive rate could be increased by male parental care, the size of female home ranges, the size and stability of female groups, and the density and distribution of females in space. Mating systems ranged from monogamy, to polyandry, to various forms of polygyny and polygynandry.

In obligate monogamy, one female defends a territory and is defended by a single male (e.g., some gibbons, prairie voles). In polymorphic monogamy/polygyny, females are solitary and dispersed, but sometimes one male can defend multiple females (e.g., galagos). In polyandry, females are solitary and defend a territory, but two or more males codefend the females territory (e.g., African wild dogs). In unimale polygyny, females form small groups (and are often territorial), and a single male is able to monopolize that group of females (e.g., yellow-bellied marmot). In multimale polygyny, females form relatively large groups (again, often territorial), and it generally requires groups of males to successfully defend the large female group (e.g., African lions). In some cases of multimale polygyny, males in a group of males defending the group of females are able to monopolize access to individual females within the group (e.g., Cape buffalo). In harem polygyny, females form non-territorial groups of small size, and one male defends the group (e.g., red deer), and in general polygyny, female groups are too mobile to be defendable, and so males defend resource-based territories in regions that females frequently pass through (e.g., zebra). Finally, in lek mating systems, females exist in large, unstable groups that move through

undefended ranges. In this situation, local female densities can be very high, and males defend small, non-resource-based territories where they can display to females. Females may sample multiple male display sites before choosing a particular male to mate with (e.g., Uganda kob).

Avian Mating Systems

In contrast to mammalian systems, most birds have biparental care, and social monogamy is the most common social mating system (e.g., Lack 1968). However, the advent of genetic fingerprinting analysis quickly revealed that genetic monogamy was actually quite rare (e.g., Gibbs et al. 1990). Hence, the actual mating system often involved both multiple mating (polygyny) on the part of males and on the part of females (polyandry). In spite of this, pair-bonding and biparental care does seem to provide important benefits to offspring (and to increase the reproductive success of parents) in many species.

With respect to the social mating system, initial efforts to classify avian mating systems focused on the polygyny threshold model (Verner and Willson 1966; Orians 1969). Under this model, females choose among males that vary in some aspect of quality (typically the quality of resources on the male's territory). Depending on the difference in reproductive success between mating with a low or high quality male, females may prefer to mate with a high quality male as a second mate (even if secondary females do not have equal access to the male's resources), rather than mate with a low quality male in a monogamous pair (this is the polygyny threshold). Some studies have provided evidence that supports the predictions of the polygyny threshold hypothesis for specific taxa. For example, in red-winged blackbirds (Pribil and Searcy 2001 and references therein), there is evidence that female settlement patterns are influenced by male mating status (females showed a preference for monogamous males when matched by quality against polygynous males). Removal experiments demonstrate that polygyny does impose a cost on females. Pribil and Searcy (2001) experimentally

manipulated variation in male territory quality to show that it influences female choice.

However, in other cases the predictions have not been supported, and researchers have proposed alternative hypotheses. For example, Altmann et al. (1977) proposed that female reproductive success might increase with harem size, especially if females engaged in cooperative territory defense. Evidence to support this hypothesis was found in yellow-rumped caciques.

Even when there is a cost of polygyny to females, the polygyny threshold hypothesis may not apply. For example, in pied flycatchers, Alatalo et al. (1982) proposed that females could not recognize whether a male had already mated or not (deception hypothesis). Alternatively, it was proposed that females were unable to find unmated males, or unable to drive off secondary females (Stenmark et al. 1988).

Mating Systems and Sexual Conflict

Davies (1989) proposed a synthetic hypothesis to explain levels of both polygyny and polyandry that focused on the costs and benefits of polygamy to both sexes when both sexes provide parental care (in addition to the effect of the dispersion of resources on male territory quality and female dispersion patterns). Davies (1989) used the example of the Dunnock, which shows extreme variation in mating systems within populations, to illustrate his arguments. Dunnock females and males attempt to extract parental investment from one or more members of the opposite sex. Polyandrous females that are able to attract two males to assist with offspring care have higher reproductive success than monogamous females. Polyandrous females maintain mating relationships with both males, but under some circumstances both males are better off tolerating this uncertainty of paternity rather than seeking a monogamous relationship. Symmetrically, polygynous males that can defend the territories of two females and mate exclusively with both females have higher reproductive success, but at some cost to the average reproductive success of his mates. Hence polyandry (polygyny) provides a benefit

to females (males), but a cost to males (females). Monogamous pairs also occur, as do polygynandrous groups (rarely) consisting of territorial groups of females and males. Variation in the mating system among groups appears to be controlled by a mix of different factors, including variation in individual competitive ability, the adult sex ratio, and environmental conditions such as the density of vegetation.

The argument that sexual conflict, and the resulting struggle over parental investment by males and females, strongly affects mating systems has become widely accepted. Brown et al. (Brown et al. 1997) developed a theory of mating system evolution that incorporated sexual conflict as a key component. They viewed mating systems as a set of adaptations designed to maximize the reproductive success of members of each sex, in the context of the resolution of sexual conflicts. They noted that conflict can occur at many different points in the sequence of intersexual interactions, including pair formation (e.g., signal reliability), courtship (e.g., persistence), copulation, and postcopulatory events (e.g., cryptic mate choice). They focused on several key aspects of manipulation in the context of sexual conflict, including persuasion (e.g., offering a fitness-enhancing incentive such as spermatophores), coercion (e.g., harassment), and forcing (e.g., traumatic insemination). They viewed mating systems as a series of key interactions: typically male-male conflict sorts out which males have the opportunity to mate, female-female conflict partly determines the effectiveness of different forms of male-male conflict, and determines which females have access to male resources (e.g., male parental care), and intersexual conflict affects the effectiveness of alternative forms of intrasexual competition. For example, female control of copulation favors male display and reduced male-male competition, whereas male control of sperm precedence (e.g., via sperm scoops) favors precopulatory mate guarding. They argued that the evolution of mating systems ultimately depends on three sets of variables: the distribution of resources and mates in the context of economic defensibility (as emphasized by Emlen and Oring (1977)), the presence and

availability of material and genetic benefits that are transferred between the sexes, and which sex controls events during the mating sequence (particularly the extent to which persuasion, coercion, or forcing are effective).

Other researchers have also attempted to paint the factors affecting mating systems with a broad brush. For example, Owens and Bennett (1997) emphasized the importance of life history constraints, ecological factors, and social conflicts as factors influencing the mating systems of birds. They used a broad, phylogenetically controlled comparative analysis to argue that these different factors were useful for explaining variation at different levels in the taxonomic hierarchy. Life history constraints appear to be most relevant to explaining variation across broad taxonomic groups (e.g., precociality vs. altriciality may explain differences at broad (family level and above) evolutionary scales). Differences in ecology are more likely to explain differences at lower taxonomic levels, such as variation among species. Finally, variation in the nature and level of social conflicts was more frequently associated with mating system variation among populations within a species.

The Evolution of Polyandry

While polygyny was the focus of mating systems theory early on, in the last several decades interest in polyandry has accelerated, and recent evidence suggests it is a widespread phenomenon, although variable in frequency among taxa (Taylor et al. 2014). In some systems, such as *Drosophila*, polyandry can impose severe costs on female fitness (e.g., Rice 1996). Even in this case, polyandry (promiscuity) is common. However, in other species females suffer no apparent costs and are likely to benefit from polyandry (Lemaitre and Gaillard 2013). For example, polyandry may enable females to acquire more male parental care than they would in a monogamous relationship, as in the Dunnocks described above (Davies 1989). Many other hypotheses concerning the evolution of polyandry have been proposed, and it is likely that different factors have favored its evolution in

different taxa. A recent meta-analysis of the genetic effects of polyandry provided some evidence (depending on assumptions) for both direct and indirect fitness effects of polyandry (Slayter et al. 2012). Other factors may favor the evolution of polyandry in specific taxa.

Beyond polyandry, some species have evolved what some call “Classical Polyandry,” which is associated with sex-role reversal, in which females are more aggressive than males in competition for mates, and males carry out most of the parental care provided to offspring (e.g., jacanas, pipefish). Andersson (2005) proposed a three step model to explain the evolution of classical polyandry: (1) the evolution of male parental care (possibly driven by different factors in different taxa), (2) females become capable of producing more eggs than a single male can care for, and (3) females evolve to compete to provide clutches to more than a single male. Although rare, this appears to have resulted in sex-role reversal in a number of species widely dispersed across the tree of life.

Lek Mating Systems

Another form of polygamy that has received considerable attention from theorists involves lek mating systems (Hoglund and Alatalo 1995). In these systems, males occupy and defend very small territories without resources valuable to females. Females typically observe and approach several males before mating and appear to be highly selective. Male mating success on leks is usually highly skewed, with a few males getting a large proportion of the matings. Lek mating systems are not common, but occur in mammals, birds, amphibians, and insects, so the system is widespread in nature. The factors which are key in the evolution of lek aggregations have been the subject of debate. Working on sage grouse, Gibson (1996) proposed that leks form when males settle on “hot spots,” where females are likely to encounter males during travel between their wintering and nesting ranges. Beehler and Foster (1988) proposed that some males may have especially attractive displays (“hotshots”), and other males may aggregate around these males to attempt to attract some of the many females

attracted to the hotshot male. Finally, others (reviewed in Hoglund and Alatalo 1995) have suggested that females may select for male aggregations because the aggregations allow them to select among a range of males of varying quality and select the best one. Another possibility is that females prefer to select mates in specific places that are safer for them in terms of risks of predation or parasitism. These different hypotheses are still being tested in a variety of taxa, and it is likely that different explanations apply to different species.

Human Polygamy

The mating system of early hominids is the subject of much debate, with some researchers arguing that pair-bonding and monogamy likely characterized the hominin lineage from early on (e.g., Reno et al. 2003), whereas others argue that early hominins were likely polygynous (e.g., Gordon et al. 2008). Early humans may also have been mainly monogamous, probably due to ecological constraints on the ability of a single male to support multiple females. There is some evidence from comparative studies of hunter-gatherers to support this idea (e.g., Walker et al. 2012).

Whatever the early human mating systems were like, the advent of sedentism and agriculture was associated with a major change in human mating systems across the world, with extreme polygyny developing in multiple societies in step with increasing levels of wealth accumulation, cross-generational transfer of wealth, and the size and complexity of social hierarchies (Betzig 2014). As Betzig describes, all of the major foci of civilization were characterized by having despotic reproductive hierarchies in which the (male) rulers had large numbers of mates (wives or concubines) and produced extraordinary numbers of offspring. In China, for example, emperors had access to literally thousands of women. Genetic evidence suggests that one in 200 men carry Y chromosome material inherited from the emperor Kublai Khan, who had a truly phenomenal number of offspring and descendants (Betzig

2014). Other civilizations, such as those in Egypt and India, showed similar levels of reproductive skew. Working down the hierarchy, males had progressively smaller numbers of mates. Given the roughly even sex ratio that characterizes human populations, this meant that there were vast numbers of males at the bottom of the hierarchy that had no mates, in many cases for life (Betzig 2014).

Many traditional cultures show some level of polygyny, and a number of researchers have focused on the causes and consequences of polygyny in traditional human societies, particularly in Africa (e.g., Strassmann 1997). While many cultures across the world still accept some level of polygyny, and some cultures even exhibit polyandry (e.g., Tibet), monogamous marriage has come to characterize the most populous cultures of the modern world. A variety of factors have been proposed to explain this trend, but that is beyond the scope of this entry (see entry on ► “monogamy”).

Polygamy in Humans

Definition

Mating systems in which a member of one sex associates with multiple members of the other sex.

Introduction

There is little doubt that the “natural” mating system for human beings is polygamy, which includes two different reproductive arrangements: polygyny and polyandry. In polygyny, one man mates with more than one woman, a “harem” as traditionally understood. In polyandry, one woman mates with more than one man. Neither implies promiscuity, since both polygyny and polyandry involve establishing some sort of long-standing relationship.

Evidence for Polygyny

The evidence for human polygyny comes from several independent sources:

1. Sexual dimorphism, the pattern in which the sexes are phenotypically distinct, typically with males larger than females, and – in other animals – often outfitted with anatomical weaponry. Men are, on average, 20 % larger than women, with this difference greater yet with respect to muscle mass. Although such dimorphism does not in itself prove polygyny, it is consistent with male harem formation, since in such a system, male-male competition generally selects for traits leading to success, with greater size and strength often being positively favored. It is also noteworthy that there is a positive correlation between the degree of polygyny (average harem size) and degree of sexual dimorphism, when comparing closely related species this provides added confidence in the significance of sexual dimorphism as an indicator of polygyny.
2. Behavioral dimorphism, the nature of male–female differences in behavior. Physical dimorphism, in itself, would not enhance male fitness if it were not correlated with behavioral dimorphism, notably a greater male tendency toward aggressive behavior, since it is only in concert with behavior that physical endowment facilitates access to females. And in fact, boys and men are significantly more aggressive – even violent – than girls and women.
3. Sexual bimaturism, the difference in age at sexual maturation between girls and boys. Given that women (and female mammals in general) make a larger physiological and metabolic investment in pregnancy and lactation, it would seem that they would become sexually mature later than men, since the latter are required to make a much smaller investment in reproduction. But the pattern is reversed: girls become sexually and socially mature several years earlier than boys. As with evidence 1 and 2, this pattern is consistent with polygyny, since even though a male's biologically mandated investment in reproduction is much less than a female's, polygynous systems impose male-male competition, such that males are more fit if they delay entering the competitive arena until they are large, strong, and perhaps experienced enough to succeed.
4. Prior to the cultural homogenization imposed by Western colonialism, approximately 83 % of traditional societies endorsed polygyny. This does not mean that 83 % of men were harem keepers but that a small number of men would have been disproportionately represented as progenitors (Murdock 1967).
5. There is considerably more genetic variation in mitochondrial DNA (contributed through the maternal line, via egg cytoplasm) than in Y chromosome DNA (Dupanloup et al. 2003). This strongly suggests that the variance in women's reproductive success was less than the variance in its male counterpart – once again, strongly suggesting an important historical role of polygyny.

Evidence for Polyandry

By contrast, the biological evidence for polyandry is more diffuse but nonetheless suggestive.

1. Human beings are unusual among mammals in that females conceal their ovulation. In most species, ovulation is conspicuously advertised, but not in *Homo sapiens*. Although there is debate as the reason for this, one possibility is that whereas conspicuous ovulation would have led to sexual monopolization by one man, such “mate guarding” cannot be effective throughout the ovulatory cycle, so that concealed ovulation enabled ancestral women to mate on occasion with men other than their designated partner (Barash and Lipton 2009).
2. Women are also unusual among mammals in lacking a clear behavioral estrus (or “heat”) cycle. As a result, they are able to exert a remarkable degree of control over their choice of a mate, unlike most female mammals, who find themselves helplessly in thrall to their hormones. Absent such choice, polyandry

would be indistinguishable from literal promiscuity.

3. Recent studies by evolutionary psychologists have shown that during their ovulatory phase, women are attracted to men whose body build and facial features reflect high testosterone and basic good health (that is, good genes), whereas otherwise, they are more influenced by indications of intelligence, kindness, sense of humor, ambition, and personal responsibility. In other words, women follow a two-part reproductive strategy consistent with an evolutionary history of polyandry: mate, when possible, with partners carrying those good genes, but associate socially with those offering the prospect of being good collaborators and co-caretakers of children (Thornhill and Gangestad 2008).
4. The adaptive significance (evolutionary payoff) of female orgasm has long been debated. Among the possible explanations – all consistent with polyandry – is that orgasm enables women to assess the appropriateness of a short-term mating partner as a long-term prospect, while another suggests that female climax is not only rewarding for the woman in question but also reassuring for her partner, providing confidence that she will be sexually faithful while giving her the opportunity to be the opposite.
5. Given that polyandry among animals is predictably correlated with reversals in the “traditional” forms of sexual dimorphism, why has not human polyandry resulted in women being larger and more aggressive than men? For one thing, it is not possible for men to be larger than women (which is mostly a result of polygyny) and for women to be larger than men (because of polyandry). And for another, because of the higher variance in male fitness, the reproductive payoff to polygyny – and its associated male-male competition – is substantially greater than that of polyandry, which in turn has likely caused polygyny to be the more prominent driver of human sexual evolution. This is not to claim that polygyny (acting mostly on men) is any more real than is polyandry (acting mostly on women), but rather

that its effects are more dramatic and more readily identified.

6. Because of the negative fitness consequences for men resulting from polyandry on the part of “their” women, we can expect that men would have been selected to be quite intolerant of it. And indeed, sexual jealousy is a pronounced human trait – also widespread among animals – not uncommonly leading to physical violence. Such a powerful and potentially risky emotional response would not have been generated by evolution if women were not predisposed, at least on occasion, to behave in such a way that is adaptive for them.

Advantages of Monogamy

Although polygamy is more “natural” for human beings, monogamy has much to recommend it, mostly because it increases the likelihood of male involvement in child rearing, something that is otherwise rare in mammals because males, unlike females, lack evolutionary confidence in genetic relatedness to their purported offspring. Human beings also possess an array of proximate mechanisms that permit monogamy and even, under some circumstances, encourage it (Barash 2016). Moreover, a strong case can be made that human beings might be at their best when doing things that are “unnatural,” such as learning to play the violin, to speak multiple languages, and also, perhaps, when resisting their polygamous inclinations.

Conclusion

There is little doubt that human beings are “naturally” inclined to polygamy, apparent as both polygyny and polyandry. Although the impact of polygyny (male “harem” formation) is more immediately evident, there is strong evidence for simultaneous polyandry as well (in which a woman mates with more than one man). Worth emphasizing, however: the fact that polygamy is natural to *Homo sapiens* does not argue against the adaptive value, the desirability, or the

feasibility of monogamy. Human beings, perhaps alone among animals, are capable of consciously resisting their inclinations – and are empowered to do so in proportion as those inclinations are understood.

Polygyny and Effective Population Sex Ratio

Daniel Kruger
University of Michigan, Ann Arbor, MI, USA

Synonyms

[Mating market](#)

Definition

When men can have multiple female partners, the ratio of available women to available men in a population is reduced compared to the raw population proportions.

Introduction

Most mammalian species are polygynous, where a male can simultaneously have several female mates (Reichard and Boesch 2003). In polygynous species, male reproductive success is more highly skewed than female reproductive success, both because of high status males with multiple mates and because fewer potential partners are available to lower-status males.

Reproductive Dynamics

The operational sex ratio (OSR) was defined across species as the number of sexually active males per 100 sexually receptive females in a

particular population (Emlen and Oring 1977). Researchers have operationally defined the human sex ratio in terms of raw population counts (e.g., Barber 2000) and as an effective sex ratio in the mating market, e.g., the ratio of unmarried men to unmarried women (e.g., Kruger et al. 2010).

The economics of supply and demand give greater leverage and bargaining power to the rare sex (Fisher 1930); however, because the reproductive strategies of men and women are somewhat divergent, imbalances in the sex ratio exhibit directional effects consistent with the strategies of each sex. There is more competition among men to demonstrate that they are committed long-term relationship partners and providers when women are scarce (Pedersen 1991). Men with lower social status and less abundant resources are even less likely to be married when the sex ratio is male biased (Pollet and Nettle 2007).

In polygynous species, some males will have many offspring, while many others will have none, creating powerful selection pressure for traits that lead to success in mating competition at the expense of longevity (Plavcan 2000). Primates vary considerably in the degree of polygyny; humans have a moderate degree of polygyny (Betzig 1986). Still, men's reproductive success is more variable than women's reproductive success; resulting in male mating competition as a potent force of selection. Polygyny occurs in the vast majority of cultures (84%) documented by anthropologists (Ember et al. 2007).

The higher the degree of polygyny in a population, where high status men are better able to attract and/or retain multiple female partners, the higher the effective sex ratio will be. For every woman who is polygynously mated, there is one less woman available to other men. A polygynous population with a numerical balance of reproductive aged men and women may have an effectively male-biased sex ratio (Hendrix 1996). The degree of polygyny will constrain the effects of female numerical surplus, as well as accentuate male competition in balanced or male-biased populations. Higher degrees of polygyny are

associated with greater consequences of male mating competition (Kruger 2010).

Conclusion

Higher degrees of polygyny correspond to an effectively higher (more male biased) sex ratio, increasing the intensity of male mating competition.

Polygyny and Male Risk-Taking for Status

Daniel Kruger

University of Michigan, Ann Arbor, MI, USA

Synonyms

[Male mating competition](#)

Definition

When men can have multiple female partners, male reproductive success is more highly skewed, and male mating competition is more intense.

Introduction

Among mammals and most other animals, females are the limiting sex in reproduction because they provide almost all of the physiological resources required for offspring production. The larger investments allocated to offspring result in much lower potential reproductive capacities in females compared to males. Because of these factors, females are more discriminating in mate selection, and males exert comparatively more effort than females in attracting and retaining mates (Bateman 1948; Trivers 1972).

Although men provide less parental investment in offspring than women, human paternal investment is considerably larger than that of most other primate males (Buss and Schmitt 1993). Altricial human offspring require tremendous parental investment, and the value of the male contribution to this investment is indicated by the higher mortality rates (Hill and Hurtado 1996) and lower reproductive success (Geary 2005) among children who grow up without a father present.

Preferences for certain characteristics in selecting romantic partners are in part a reflection of the value that men and women provide in reproductive relationships (Buss 1989). Women

prefer men with cues of ability and willingness to commit to long-term relationships and substantial paternal investment (Buss 1989). Males with higher social status and greater economic power have higher reproductive success across a wide variety of societies (Hopcroft 2006). Thus, men compete for social status and resource control, and greater inequality leads to greater risk-taking in the service of this competition (Kruger and Nesse 2006). The degree of polygyny, related to the degree of male reproductive inequality, intensifies risk-taking related to male mating competition (Kruger 2010).

Human Reproductive Dynamics

Males compete more intensely for female sexual partners in most animal species because females usually invest more in offspring and are therefore selected to be more discriminating in selecting mates (Bateman 1948). Male mating competition can involve fights with other males for rank or territory; it can also involve competition over traits and displays that females prefer in their mates. Males succeeding in these competitions have more offspring, shaping traits that foster such success, even if those traits also have detrimental consequences (Darwin 1871). Thus, sexual selection helps explain sex differences in psychology and behavior, including greater male tendencies for risk-taking, competitiveness, and sensitivity to social hierarchy (Cronin 1991).

Both women and men share preferences for partner characteristics such as kindness, understanding, and intelligence (Buss 1989); however, male and female preferences also show divergence following reproductively relevant currencies. Human paternal investment is near the high end of the spectrum for mammals, especially for primates (Low 2003). Paternal investment may enhance offspring survival (Hill and Hurtado 1996) and reproductive success (Geary 2005). Thus women prefer males with higher social status and resource control as marriage partners, because of their high potential for investment (Buss 1989). Culturally appropriate indicators of male social status and economic power directly

predict reproductive success across a wide variety of societies (see Hopcroft 2006). Variance in male wealth and power increased over historical time through sociopolitical arrangements and intergenerational transfer (Smuts 1995).

Greater variation and skew in male social status and resource control produces greater competition for positions of power and status. This heightened degree of competition leads to higher levels of risk-taking, with resulting detrimental consequences for mortality (Kruger 2010). Socio-economic status has a stronger influence on mortality rates for men than for women (Kruger and Nesse 2006; Martikainen et al. 2001). Increasing uncertainty of economic opportunities and increasing variability in male social status and resource control within populations are also associated with elevated male mortality rates (Kruger and Nesse 2007).

Polygyny

Polygyny is the most common mammalian mating system, likely because of female specialization in infant nutritional provisioning and care and male specialization in mating effort (Low 2003; Reichard and Boesch 2003). The degree of polygyny is analogous to male reproductive inequality. In highly polygynous species, a few males will have many offspring, whereas many others will have none (Reichard and Boesch 2003). This highly skewed reproductive success creates powerful selection pressure for traits that lead to success in mating competition. Such selection pressure has produced elaborate ornaments (such as the peacock's tail) and armaments (such as a deer's antlers), all with substantial costs. The elephant seal is an archetypal example of a highly polygynous species. The disproportionately large males compete intensely for large harems of females, and most males die before reproducing.

The longevity gap between male and female vertebrates is highest among polygynous species (Clutton-Brock and Isvaran 2007). Most mammalian species are polygynous, where a male can simultaneously have several female mates (Reichard and Boesch 2003). In polygynous

species, male reproductive success is more highly skewed than female reproductive success, both because high status males can obtain multiple mates and because fewer potential partners are available to lower status males. Male elephant seals have over four times as much variance in reproductive success as females (Le Boeuf and Reiter 1988). The intense male mating competition in polygynous species selects for strategies that enhance competitive success at the cost of longevity (Williams 1957). Across species, higher degrees of polygyny correspond to greater male-male competition and higher levels of risky male behavior (Plavcan and van Schaik 1997), larger size and armor of males, and exaggerated male mortality rates compared to females (Leutenegger and Kelly 1977).

Human Polygyny and Risk-Taking

Humans are less polygynous than most other primates, but the variation in male reproductive success is still substantially higher than that for females (Betzig 1986). A small number of high status men have a disproportionately high number of mating partners, and the positively skewed distribution of male reproductive success makes mating competition a potent selection force (Betzig 1986).

Polygyny occurs in the vast majority of cultures (84%) documented by anthropologists (Ember et al. 2007). Human populations vary in their degree of polygyny, covarying with pathogen stress and male mortality in warfare (Ember et al. 2007). Polygyny is most prevalent in human societies when there is substantial inequality in resources and social status (Orians 1969). Increased sexual dimorphism, where males are larger than females, is directly and positively related to the level of male mating competition (Bribiescas 2006). Human females are on average 80% as large as males (Clutton-Brock 1985).

The degree of polygyny reflects the intensity of male mating competition, which in turn is associated with higher levels of risk-taking and greater male mortality rates (Kruger 2010). Some of this risk-taking is through physical violence, which is

a facet of human male mating competition both within and between groups (Chagnon 1992). Men can successfully use violence to elevate their social status and gain respect (Campbell 1993; Chagnon 1992; Hill and Hurtado 1996). Violence may result from competition over access to and control of resources, as well as position in the status hierarchy (Buss and Shackelford 1997). Greater nonviolent risk-taking, leading to higher numbers of accidents, results in greater male mortality rates. This is especially prevalent in young adulthood when males are entering into mating competition (Kruger and Nesse 2004, 2006).

Conclusion

The degree of polygyny in a population influences the intensity of male mating competition; greater competition for status leads to riskier behavioral and physiological strategies.

Definition

The polygyny threshold is the minimum difference in quality of male territories that is sufficient to make a female choose to mate with a male that is already mated, instead of mating with a male that has no mates.

Introduction

For decades, polygynous mating systems – in which a male is paired to two or more females – were seen as a reflection of the population sex ratio. Under this rationale, a 1:1 adult sex ratio (one male for each female in the population) would predict that males would mate, on average,

with one female during the breeding period, and females would behave the same way; i.e., the mating system would be monogamous. Following this rationale, in a biased sex ratio scenario of 1:3 (one male for three females), it would be expected that males would acquire more than one mating partner; i.e., a polygynous mating system would be predicted. However, through the accumulation of data on sex ratios and mating system characteristics, it was noted that there are cases that rebut the already mentioned rationale to explain the evolution and development of polygynous mating systems. For instance, there are monogamous species with biased sex ratios, and polygynous species with even sex ratios.

In the light of the inconsistency of the sex ratio hypothesis, in the 1950s, researchers started to develop hypotheses to explain the evolution of polygyny. Verner (1964) noticed that in a population of the long-billed marsh wren, *Telmatodytes palustris*, despite the even sex ratio, there were several cases in which females chose already mated males, while there were unmated males available. If females choose a mated male instead of a bachelor, they should gain fitness benefits from this behavior and, thus, there should be selection acting on females to mate polygynously. Given this scenario, Verner (1964), and Verner and Willson (1966) developed the hypothesis that when differences exist in the qualities of male territories, if the difference between two territories is large enough, females will choose the male in the better territory even if this territory already has a female and the other territory has no females. This led to the idea that there must be a threshold that determines whether a female must remain in monogamous relationships or join polygynous ones, i.e., the polygyny threshold.

From Monogamy to Polygyny

Every trait or behavior that enhances the fitness of an individual is expected to be selected. If a male acquires more offspring by mating with several females, one can expect the evolution of polygyny. However, if the male provides parental care to the offspring, the evolution of polygyny may be

disadvantageous to females, given that a polygynous male will have to share his parental effort among the offspring obtained with different females – each female receives less help than she would obtain in a monogamous relationship. If polygyny is disadvantageous to females (i.e., reduces their fitness), one can expect polygyny to be counter-selected.

If a female in a polygynous group receives less help in caring for her offspring, what could also make polygyny advantageous to females, to the point that polygyny would be selected? Mating with already mated males would be expected in situations in which the female may gain greater direct (e.g., food, protection, nest sites) and/or indirect (e.g., genes of higher quality to her offspring) benefits from polygyny. Given the potential benefits, females should choose among males basing their decision on: genetic male quality, potential paternal care, and the quality of the territory held by each male. Every time these benefits overcome the costs of polygyny (e.g., less help in caring for young, greater competition for resources), polygyny is expected to evolve. This evolution is likely to take place when there is variance in the distribution of a particular resource (e.g., food) in the environment. Such variance allows the existence of territories that contain greater amounts of resource than others. Once the territories are different in quality, if the male population is large enough, some males will occupy low-quality territories. Once males occupy territories that vary in quality, they cannot offer equivalent reproductive benefits to females.

Hypothetically, the first female to choose a mate has all the n mature males available to her choice. If the territories held by these males differ in quality, the female is predicted to choose the male holding the best territory. The second female to make a choice faces a different situation; she may choose between a number of $n - 1$ unmated males, and one mated male holding the best territory. If this second female gains more offspring by choosing the male with the second best territory than mating with the mated male, she is expected to become monogamous. However, if despite the costs of sharing the best territory with another female, the second female gains more offspring

by choosing the mated male with the best territory instead of the bachelor holding the second best territory, she is expected to establish a polygynous relationship. This shift from monogamy to polygyny is created by the differences in quality between the males' territories. This polygyny threshold can only be crossed once a female joining a polygynous group can achieve reproductive success at least as high as if she would by mating with a bachelor. If the differences in territory quality are of great magnitude, it is possible that some males will be able to monopolize a larger proportion of females, leading some low-quality males with low-quality territories to stay unmated.

The Polygyny Threshold Model

The polygyny threshold model (PTM) was developed by Orians (1969) in order to propose a hypothesis for the evolution of mating systems in birds and mammals based on individual fitness, and in opposition to a hypothesis based on group selection. Through the analyses of female choice possibilities, the PTM provides theoretical basis to predict the development of mating systems, specifically the shift from monogamy to polygyny. Polygyny is always expected to be advantageous to males, thus to understand the evolution of polygyny, one should focus on benefits and costs to females. Hence, the PTM is based on female choice.

The PTM assumes that (a) females actively choose mates; (b) if a female chooses to mate with a particular male, this choice prevents her from choosing another male; (c) if a female rejects a particular male, there is no loss in fitness, on average, as there are other males available, and the female has a high probability of mating with at least one of them; (d) the population occupies a heterogeneous environment in relation to conditions or resources relevant to reproduction, such that territory quality, and reproductive success are correlated. The PTM is explained by graphical means and contains two curves: the left and right curves represent, respectively, females in monogamous and females in polygynous groups (Fig. 1). For a given territory quality value, the fitness

Polygyny Threshold (Behavioral Ecology), Fig. 1 The polygyny threshold model illustrates the relationship between the territorial quality (or any breeding situation related to a specific available male) and female fitness. X represents the quality of the territory held by an unmated male x . Y and Z represent the respective qualities of the territories held by two already mated males, y and z . C represents the fitness costs of mating polygynously, and PT represents the polygyny threshold. $Y-X$ represents the differences in quality of the territories held by males x and y , and $Z-X$ represents the differences in quality of the territories held by males x and z . Every time the difference in quality between territories exceeds the polygyny threshold, females are expected to mate polygynously

payoff of polygynous females is always less than the payoff that a monogamous female would gain, because polygyny tends to incur costs C that are absent or not as high as in monogamy (e.g., less paternal care, increased competition from higher density of individuals sharing higher quality habitats, increased predation risk from the agglomeration of individuals in higher quality habitats). Every time the differences in territory quality exceed the polygyny threshold, the female is predicted to mate polygynously (e.g., $Z-X$ in Fig. 1). However, when the threshold is not surpassed (e.g., $Y-X$ in Fig. 1), the female should mate monogamously.

The PTM promoted a great amount of empirical tests, and received support from different sources of data, for instance: polygynous females of great reed warblers, *Acrocephalus arundinaceus*, indigo buntings, *Passerina cyanea*,

and lark buntings, *Calamospiza melanocorys*, show similar reproductive success when compared to monogamous females; the majority of red-winged blackbird females chose polygyny when they were experimentally faced with mated males with territories containing more nest sites, and bachelors with territories containing fewer nest sites; by breeding in high-quality territories, these polygynous females gained fitness benefits that surpassed the costs of mating polygynously (Pribil and Searcy 2001), which makes the polygyny option adaptive.

Counter-Evidences and Criticism

The PTM was also refuted by other studies, which leads to the idea that the applicability of the PTM may be restricted to some contexts and systems, in a way that some species and even particular populations in generally polygynous species may not behave as predicted by the model. For example, in the work of Pleszczynska (1978), some females that could mate with a mated male with a better territory chose to mate with a bachelor. In red-winged blackbirds (different study from the mentioned above), females do not even pay a cost of polygyny. Moreover, other studies report that second females to mate with the male gain lower fitness than monogamous females. Given the difficulties in interpreting the contrasting evidence, alternative or complementary hypotheses to the PTM have been proposed. For instance, it has been argued that, if females settle asynchronously in a male territory, the overlap in urgency for paternal care by each brood may be reduced, which diminishes the polygyny threshold (Leonard 1990). The sexy son hypothesis has been proposed to explain cases of lower fitness of second females (Weatherhead and Robertson 1979). This hypothesis states that a second female to cross the polygyny threshold may gain less reproductive success than a monogamous female at a first moment. But, their young will be of higher quality – since the young received alleles from a high-quality polygynous father – thus, she will gain greater fitness in future generations through the offspring of her sons.

Another limitation of the PTM is that it assumes that females may choose mates freely (i.e., PTM is an ideal free model), but, in many cases, females are not free to choose partners. For instance, second females may not be allowed to settle by resident females of mated males (e.g., red-winged blackbirds), thus they may not be able to cross the polygyny threshold. Besides that, sometimes, females may mate with an already mated male just because it is difficult to find unmated males, distinguish mated from unmated males (Alatalo et al. 1981), and/or properly sample males and territories. Lastly, contrary to the PTM, sometimes it seems that females do not suffer costs from polygyny and just settle at random, which led to a neutral mate choice hypothesis (Lightbody and Weatherhead 1988).

Conclusion

The polygyny threshold is an important idea that helped to explain the evolution of polygynous mating systems. The concept led to the development of several theoretical models, especially the PTM. This model provided theoretical base and many predictions for empirical tests. The limitations of the PTM stressed in the last four decades are important and must be considered in the construction of the paradigm. Nevertheless, the PTM and, particularly, the concept of a polygyny threshold remain key points in the continuous effort to understand the evolution of mating systems.

Definition

The polygyny threshold model (PTM) provides an explanation for the occurrence of polygyny in the animal kingdom – the mating/marriage of one male with multiple females. This model is principally applied to species, including humans, in which males provide/defend resources to provision their mates and offspring. The *polygyny threshold* refers to the minimum level of inequality in male resource holding, such that a given female's reproductive success is enhanced by becoming the second mate of a resource-rich and already paired male, rather than the sole mate of a resource-poor unpaired male. Once this threshold is surpassed and there is sufficient inequality, polygyny is predicted to occur.

Introduction

Understanding the determinants of mating and marriage systems is vital to a complete understanding of humanity, since they have been demonstrated to have knock on effects at many levels of society. These tenants of social structure bear influence on parenting strategies and family dynamics, violence and crime rates, inheritance systems, and much more. In the case of polygynous societies – where one man mates/marries multiple women – such a system is associated with decreased paternal care for offspring (Strassmann 1981), increased male-male aggression (Schmitt and Rohde 2013), and patrilineal inheritance systems (Hartung et al. 1982). The socially imposed monogamy observed in many industrialized societies today is not representative of the majority of human populations. In fact, polygyny is estimated to be permitted in more than 80 % of human societies (Murdock 1967), and therefore it is still very relevant to our understanding of human behavior.

In order to understand the evolutionary explanation for the widespread occurrence of polygyny in human societies, it is necessary to comprehend the underlying mechanisms behind sex differences in mating behavior and mate choice. The following entry will have five sections:

(1) parental investment and female choice; (2) female mate preferences; (3) women's preference for resources; (4) the polygyny threshold model, theory; and (5) the polygyny threshold in humans – empirical evidence.

Parental Investment and Female Choice

Trivers defined parental investment as *any investment by the parent in an individual offspring that increases the offspring's chance of surviving (and hence reproductive success) at the cost of the parent's ability to invest in other offspring* (Trivers 1972, p. 139). These investments include energetic investments such as producing gametes, material investments such as provisioning an offspring with nutrients, and behavioral investments such as guarding offspring from predators. Males and females have different costs of reproduction, which begin with anisogamy – the fusion of two different gametes in sexual reproduction. The male sex cell is small and metabolically cheap to produce, whereas the female sex cell is larger and more costly. Usually the female is the sex which invests more in the offspring given the initial sunk investment of the more costly sex cell (Trivers 1972). Conversely, the extent of male parental investment (MPI) varies considerably between species, sometimes being limited to the contribution of sperm, e.g., in fish species with internal fertilization, males do not participate in any brood care (Perrone and Zaret 1979); and in other cases MPI includes considerable provisioning and protection for extended periods of time, as observed in many bird species (Møller and Cuervo 2000).

Given that the male gamete is cheap and that it is usually females who invest more in offspring, males have a fast potential reproductive rate; thus, the limiting factor of a male's reproductive success is access to opportunities to fertilize female sex cells (hence, polygyny is advantageous to males since it increases these opportunities). On the contrary, female reproductive rates tend to be restricted by the production of costly sex cells and considerable investments in rearing offspring; hence access to mates is not the primary limiting factor of female fitness (Clutton-Brock and

Vincent 1991). Therefore, it is typically females who are the more choosy sex in terms of mate selection, this phenomenon is referred to as “female choice” (Trivers 1972).

Female Mate Preferences

The traits valued by females of a particular species are largely determined by the necessity of MPI for the successful siring of offspring. Among species where MPI is low and unnecessary, females will predominantly select mates based on their genetic robustness (in terms of survival and reproduction prospects), and complementarity (in terms how well matched a male and female genome are for the production of robust offspring) (Trivers 1972). However, in other species where MPI is more necessary and biparental investment is more crucial to offspring survival, alongside purely genetic characteristics, females give consideration to the ability of a male to provide high-quality parental investment (Trivers 1972). This preference explains the ubiquity of the courting ritual in which males offer females nuptial gifts that serve as demonstrations of their willingness and ability to invest resources. Such behaviors are common in species where females rely substantially on MPI, including many species of bird, and indeed in our own – the diamond engagement ring is an appropriate signal of a man’s commitment to invest resources (Lack 1940; Miller and Kanazawa 2007).

Women’s Preference for Resources

Narrowing the focus to humans, compared to the rest of the mammalian class, our species are somewhat of an anomaly – in approximately 95 % of mammalian species, MPI is very limited (Geary 2000). In contrast, whether it is manifested in the form of hunting for the next meal or paying tuition fees, paternal investment is ubiquitous and extensive across much of the spectrum of human societies. This high MPI can be attributed to the combination of two factors – the restricted

reproductive rate of women and the highly dependent nature of human children.

Due to the 9-month internal gestation period and the subsequent phase of lactational amenorrhea, women are very limited in the quantity of offspring they can produce over the course of their reproductive career. Additionally, the narrow female pelvic canal designed for bipedalism combined with strong selection for encephalization has resulted in the *obstetric dilemma* and human children being born altricial with a substantial proportion of brain growth having to occur postpartum (Rosenberg and Trevathan 2002). Thus children have an extended period of dependence, requiring extensive provisioning to support their metabolically expensive development (Kaplan et al. 2000). Therefore, women have been strongly selected to show mate preferences for men who demonstrate a capacity for high MPI and who can provide resources to maximize the quality of the limited quantity of (highly dependent) offspring they can produce. In a seminal study of 37 cultures across six continents, Buss (1989) showed that women consistently place high value on cues of male resource-holding potential.

Based on the information thus far, the evolutionary puzzle which emerges is deciphering why women would ever partake in polygyny. Polygyny provides an obvious evolutionary advantage to men since sperm is cheap and their potential reproductive rate is not restricted, and therefore access to more mates results in more potential fertilizations and higher fitness. However, for women, who are the choosy sex, it is resource access which is crucial to fitness. This begs the question of why a woman would choose to participate in a polygynous marriage given that such a system requires them to share their husband’s resources and parental investment with his other wives.

The Polygyny Threshold: Theory

As described above, in species such as humans where MPI is necessary, females require resource provisioning from their mates in order to maximize the quality of their limited quantity of

**Polygyny Threshold,
The, Fig. 1** Graphical
representation of the
polygyny threshold model
(Adapted from Orians
(1969))

offspring. Therefore, natural selection has shaped female mate preferences to place strong emphasis on male resource holding. This is the central premise of the *polygyny threshold model* (PTM) (Verner and Willson 1966; Orians 1969) – that a female’s evolutionary fitness is determined by the access to resources her mate can offer her; and her mating/marriage behavior should be shaped by natural selection to maximize her fitness. The model was first developed to explain mating systems in birds, and then latter applied explicitly to human polygyny (Borgerhoff Mulder 1988). It asserts that there is a level of inequality in male resource holding such that a female will achieve higher biological fitness being paired as the second partner of a resource-rich male than she would as the first partner of a resource-poor male. This is because with sufficient inequality, a fraction of a rich man’s resources, which are shared among multiple spouses, may be greater than the total of a poor man’s resources. This level of inequality is the *polygyny threshold*, and once it is surpassed, polygyny is predicted to occur. Therefore the PTM predicts that the incidence of polygyny in a society should be closely associated with the degree of stratification of male wealth.

Figure 1 provides a graphical representation of the PTM (modified version of the original figure from Orians (1969)). The curves reflect the relationship between a male’s resource holding and the fitness of a female pairing with him (a) monogamously (C^M) or (b) bigamously (C^B). For any given environmental quality, curve C^M is lower than curve C^B because resources must be shared if a female is paired to a male bigamously, and in turn her fitness is lower than if she was monogamously paired with him and had exclusive access to his resources. However, for each level of resources provided by an unpaired male, there is a corresponding higher level of resources provided by an already paired male which would result in a given female achieving the same fitness. For instance, a female would achieve the same fitness ($F1$) being paired monogamously to a male with resource holding $R1$ as she would being paired bigamously with a male with resource holding $R2$. Thus if this level of inequality (D) exists within a society, a female can achieve the same fitness via bigamous mating as monogamous mating and polygyny can emerge via female choice. Therefore, D represents the *polygyny threshold*.

The Polygyny Threshold in Humans: Empirical Evidence

The PTM makes three main predictions: (a) the incidence of polygyny across human societies should correlate with their relative levels of male inequality in resource holding; (b) in societies where polygyny does occur, it is resource-rich men who achieve polygyny; and (c) women marry polygynously when it is optimal for their fitness and therefore should not achieve lower fitness than monogamously paired women. All of these predictions have empirical support; however, the evidence for the final prediction is more mixed.

To begin with, there is strong support for the prediction that polygyny is more likely to occur in societies with greater male wealth inequality. At contact, Native American societies demonstrated a positive association between polygyny prevalence in a community and the extent to which males could monopolize food extraction sites, such as resource-rich fishing or hunting areas (Sellen and Hruschka 2004). This trend has even been applied at the macro level of nation-states. Schmitt and Rohde (2013) calculated a “human polygyny index” (HPI) for 38 nation-states based on the number of sexual partners reported by men and women and found a strong positive association between a nation’s HPI and their Gini index of income inequality.

Within societies with sufficient inequality, as predicted, it is the resource-rich males who marry polygynously. For instance, in Uganda, which is highly dependent on agriculture, ownership of land is a strong predictor of a man’s likelihood of having more than one wife (Pollet and Nettle 2009). Nettle and Pollet (2008) also analyzed selection gradients of wealth in 11 societies and found strikingly high selection on male wealth in the two polygynous societies from their sample, thus providing further evidence that it is indeed resource-rich males who benefit from increased mating access. Even more pronounced examples can be found in historical empires where male resource holding was extremely skewed, and emperors had access to immense wealth and in turn a vast number of mates. Dynastic leaders in

Asia had prolific concubines, and Y-chromosome research estimates that ~40 % of living Asian men may be descendants of just eleven powerful rulers from the last few thousand years (Balaesque et al. 2015).

Polygyny rates in extant hunter-gatherer societies, whose lifestyle reflects the way our species lived for the majority of human evolutionary history, are approximately 14 % (Marlowe 2005). The incidence of polygyny in this subsistence mode had previously posed a problem for the PTM since hunter-gatherers do not accumulate resources; hence, no inequality in male resource holding is assumed. However, recent research reconciles hunter-gatherer polygyny with the PTM, finding it is men with stronger social networks who marry polygynously in these groups, and these men may have superior resource access due to larger food sharing networks (Chaudhary et al. 2015).

With respect to the final prediction of the PTM, the evidence is less consistent. A woman’s evolutionary fitness is determined by both her fertility and offspring survival. There is some research indicating that polygyny can be detrimental to both of these components of female fitness and thus cannot be explained by the PTM, which asserts that it is an adaptive female choice. The polygyny-fertility hypothesis refers to the occurrence of lower fertility among polygynously married women than their monogamous counterparts, which is most likely caused by reduced coital frequency (Bean and Mineau 1986). In a review of 86 studies, 64 found evidence for the polygyny-fertility hypothesis (Josephson 2000). Moreover, the offspring of women married polygynously may also incur increased mortality risk since they have access to a smaller proportion of their father’s parental investment. The results concerning offspring mortality are inconsistent and vary cross-culturally. For instance, a study using demographic and health surveys from Ghana found that children whose fathers are married polygynously experience higher childhood mortality (Gyimah 2009); conversely, among the agropastoralist Kipsigis from Kenya, there is no significant effect of marital status on offspring survivorship (Borgerhoff Mulder 1989).

Despite considerable evidence for the polygyny-fertility hypothesis, which contradicts the PTM, the latter should not be disregarded. There are numerous potential confounding factors, which could result in the polygyny-fertility effect even if polygyny is an adaptive choice for women. For instance, women who marry polygynously are often older than those who marry monogamously, and men married to sterile wives will often marry polygynously (Pebbley et al. 1988). Additionally, Josephson (2002) found that although polygynously married women in the nineteenth-century Utah had fewer offspring than monogamously married women, they actually had the same number of grandchildren due to enhanced reproductive performance of their offspring. Thus the polygyny-fertility effect may fail to account for complex patterns governing the relationship between polygyny and women's long-term fitness.

Nevertheless, the possibility that polygyny may be detrimental to women's fitness in certain circumstances can certainly not be disregarded. Such cases may occur in settings where the rule of female choice is superseded by male coercion and thus the PTM is not applicable. In these contexts, dominant males are able to exert control over female reproductive behavior and monopolize multiple women. Among the Dogon of Mali, child mortality is a major determinant of female fitness, and the offspring of mothers married polygynously are 7–11 times more likely to die by the age of five (Strassmann 1997). Despite this, polygyny is extremely prevalent and has been attributed to the dominant position of men in Dogon society who are able to suppress female reproductive interests, i.e., male coercion rather than PTM/female choice explains polygyny (Strassmann 1997).

Conclusion

In humans, due to the restricted reproductive rate of women and the necessity of biparental care for altricial offspring, when selecting a mate, women are particularly concerned with a man's ability to provide resources. Therefore, the PTM

hypothesizes that in societies where there is sufficient inequality in men's resource holding, polygyny will emerge. This is because women will preferentially enter polygynous marriages with rich men than monogamous marriages with poor men.

The predictions of this model have mixed support from research on human populations. There is strong evidence that polygyny is more likely to occur in stratified populations and that it is rich men who marry polygynously within these societies. However, the PTM also predicts that women will choose polygyny when it is optimal for their fitness and therefore should not achieve lower reproductive success than monogamously paired women. Many studies indicate this may not be the case and that polygynously married women experience lower fertility or higher offspring mortality. These contradictory findings highlight that it is necessary to consider other models of polygyny, such as the male coercion model, in combination with the PTM for a full understanding of human marriage practices.

Autonomic nervous system; Heart rate; Parasympathetic nervous system; Phylogenetic; Respiratory sinus arrhythmia; Tenth cranial nerve; Vagal tone; Vagus nerve

Definition

The parasympathetic nervous system has two divisions affecting heart rate and general arousal, responding to novel stimuli/stressors. The older division causes freezing behaviors to novel stimuli. The evolutionarily newer division regulates social communication and self-soothing behaviors.

Introduction

Polyvagal theory was proposed by Stephen W. Porges (1995) to elucidate neurogenic control over the autonomic nervous system. Early related works assumed that the vagus nerve (tenth cranial nerve) was operated by only one neuronal control center in the brain, which is unable to explain some findings of parasympathetic functions on arousal, known as the vagal paradox, as well as being unable to explain how extreme stress can cause individuals to freeze. Polyvagal theory may overcome the vagal paradox and freezing issues by uniting under a neurogenic model of vagal regulation for orientation, attention, and emotion (Porges 1995) by assuming vagal control from multiple neuronal control centers.

In polyvagal theory, the parasympathetic system is composed of an evolutionarily older system and an evolutionarily newer system (Porges 1995). Multiple systems mean multiple neuronal nuclei feeding the vagus. Although only two systems are assumed in the model, several different nuclei in the medulla feed the vagus both afferently (receives signals from the body) and efferently (sends signals to the body) (Porges 1995). The evolutionarily older system causes freezing behavior common to lizards reacting to predators/prey; the evolutionarily newer system allows mammals to build social ties by dampening the effects of the sympathetic nervous system when no environmental threats are perceived (Porges 1995). The two systems in polyvagal theory are most noticeable in efferent pathways, showing a clear phylogenetic split between reptiles and mammals.

Vagal Tone

Vagal tone is the amount of activity traveling through the vagus nerve at any given time. The vagus, being part of the parasympathetic system, is used to measure the amount of parasympathetic activation (Porges 1995). Vagal activity is typically not measured directly, but because the vagus innervates the sinoatrial node of the heart (controls heart rhythm), heart rate and heart rate

variability have been the most widely used measures to assess vagal activity (Porges 1995). Heart rate can be viewed as tonic (producing muscular contraction) vagal control over the heart, whereas heart rate variability can be viewed as phasic (short-term step in the full tonic process) vagal control of the heart (Porges 1995). Decreases in overall heart rate are caused by high tonic vagal tone. In terms of heart rate variability, respiratory sinus arrhythmia (RSA) is used. Inhalation briefly suppresses vagal activity, causing a brief increase in heart rate, whereas exhalation resumes vagal activity, leading to a brief decrease in heart rate. The greater the difference in heart rate between inhalation versus exhalation, the greater the RSA and therefore higher vagal tone.

Vagal Paradox

The issue with taking heart rate or heart rate variability measurements is that they should both represent vagal activity, but within the interactions lie contradictions. The paradox is such that (1) increases in vagal tone are correlated with bradycardia (extreme slowing of heart rate) and (2) decreases in vagal tone are correlated with low RSA; (3) however, bradycardia can occur during periods of low RSA (Porges 1995). Therefore, if vagal activity was only controlled by one neural system, then bradycardia and RSA should happen in tandem, but they often do not.

Polyvagal Theory

Afferent Pathways: Neuroception

Because efferent pathways only make up 20 % of the vagus, 80 % are afferent fibers (Porges 2007). Although the brainstem is responsible for functions below conscious awareness (i.e., heartbeat and digestion), perceptions received at this level nonetheless cause the brain to react noticeably, through emotions and alertness. From this perspective, animals may not always know what has roused or relaxed them because this perception happens unconsciously. This unconscious perception of one's body and surroundings has been termed neuroception (Porges 2007).

Neuroception is vital for animals to quickly assess the amount of risk one is at, at any given time. Sympathetic and amygdalar pathways are also fed information via this route, causing neuroception in both arousal and emotional activation (Porges 2007), putting the body in the proper state of arousal given their unconscious assessment of the environment. Once risk is assessed, information is sent along efferent vagal pathways for immediate action, only inhibited by later, conscious, assessment of the environment.

Efferent Pathways: Phylogenic Differences

Polyvagal theory is based on the idea that there are several control centers on the medulla with projections on the vagus, giving the vagus multiple functions. The main idea is that there are two different efferent motor systems of the vagus that affect the body: one is evolutionarily older, common to all vertebrates, known as the dorsal vagal complex (DVC); the second is evolutionarily newer, mainly only distinguishable in mammals, known as the ventral vagal complex (VVC) (Porges 1995).

DVC The DVC originates in the dorsal motor nucleus of the medulla. It is the evolutionarily older system that is common to all vertebrates, innervating subdiaphragmatic organs (organs distal to the diaphragm, i.e., stomach and intestines) as well as the sinoatrial node of the heart. This system becomes active when orienting toward predators or prey, in order to slow down heart rate and conserve energy, tracked by measurements of bradycardia. However, it is unmyelinated, causing its signals to be slow and lingering (Porges 1995).

VVC The VVC originates in the nucleus ambiguus of the medulla. It is the evolutionarily newer system which is most observable in mammals. The VVC innervates supradiaphragmatic organs (superior to the diaphragm, i.e., lungs and esophagus), the sinoatrial node, as well as muscles related to vocalization and facial expression. This system becomes active during socially affiliative behaviors such as social communication and self-

soothing. It also acts as a vagal brake, keeping mammals from becoming overactive when inappropriate. This system's activity is tracked by RSA measurements (Porges 1995).

Vagal Brake

The VVC's inhibitory effects on the sinoatrial node of the heart inhibit the hypothalamic-pituitary-adrenal axis, effectively dampening the effects of the sympathetic nervous system when mammals are comfortable and relaxed (Porges 1995). Since the VVC is myelinated, its influence over the heart is immediate, versus the influence of the unmyelinated DVC. The fast-acting effects of the VVC allow it to quickly and repeatedly increase and decrease vagal tone. These rapid, instantaneous changes to heart rate are what characterize RSA (Cheng and Powley 2000). This also means rapid changes in sympathetic activation for mobilization. When the VVC is active, it creates a relaxed state for focusing on a particular stimulus; when the VVC is inactive, it allows for mobilization to change focus to another stimulus or engage with the stimuli in a different manner.

Phylogenetic Hierarchies

Because RSA is not observed in reptiles and other non-mammals, RSA is thought to be a phylogenetically evolved trait in mammals, giving RSA a separate control mechanism from bradycardia (Porges 1995). However, since both RSA and bradycardia are parasympathetic, that means the vagus has separate branches in mammals, a phylogenetically old tonic control branch and a phylogenetically newer phasic control branch. Different branches of the vagus also mean different parasympathetic control centers in the brain. In reptiles, the dorsal motor nucleus and the nucleus ambiguus are not separated, with efferent projections only coming from the dorsal portion (Porges 2007).

The phylogenetic development of the autonomic nervous system in vertebrates likely

happened in three stages. The primitive autonomic system, common to most vertebrates, is the DVC, responsible for immobilization behaviors by causing bradycardia. This is usually a fear response, causing an animal to freeze (death-feigning), or an orientation response to blend in with surroundings while stalking prey (more typical of reptilian “sit and wait” stalking than mammals stealthily tracking). Next is the sympathetic nervous system, present in all animals, but with phylogenetic increases in complexity up the evolutionary path. This system is operated by the spinal cord and endocrine system (i.e., adrenals in vertebrates); it is responsible for mobilization and fight-or-flight behaviors. The most phylogenetically evolved system, predominantly seen in mammals, is the myelinated VVC, responsible for vagal brake behaviors. Since the vagal brake allows for more rapid interactions between the sympathetic and parasympathetic systems, this catalyzes more complex behaviors typical of social interactions and self-soothing (Porges 2007). Recall that the VVC also innervates muscles related to vocalization and facial expression, as evidence of its relation to social behaviors.

From the polyvagal perspective, reptiles and mammals use opposing vagal strategies to survive. Reptiles, with low metabolic demands (low oxygen need from organs), typically have low vagal tone in order to traverse their environment (using the sympathetic system), only increasing vagal tone to novel stimuli, causing a freezing state, via bradycardia. This state is beneficial to them both defensively and offensively so that other animals cannot see them, be it predator or prey. Mammals, on the other hand, have high metabolic rates, so if the sympathetic system was given full control, then mammals would be in a constant state of high activity. Thus, mammals typically have high vagal tone, due to the vagal brake, in order to keep the sympathetic system dampened until needed. Reptiles can survive in prolonged bradycardic states, whereas mammals, with high metabolic demands, can only survive brief periods of bradycardia. Prolonged bradycardia in mammals would cause hypoxia, leading to

death. Alternatively, if reptiles did possess a vagal brake over the heart, their already low metabolic state plus the vagal brake would render them immobile, regardless of threat level (Porges 1995).

The Jacksonian principle states that phylogenetically newer systems inhibit older ones; however, older systems are not lost, but kept as backups in case the newer system fails (Porges 2007). Therefore, in mammals, when the VVC is found to be ineffective for survival, such as in situations of threat, the sympathetic system takes over. Further, one problem prior theories could not explain was why during *extreme* threat and trauma, mammals tend to freeze. Given the Jacksonian principle, this freezing behavior in *extreme* situations is the failure of both the VVC and the sympathetic system, leaving the DVC as the last resort (Porges 2007), causing a reptilian-like behavior to *extreme* threat or excitement.

Another relic of the reptilian brain in mammals can be seen in the orientation reflex. Both mammals and reptiles orient reflexively to novel stimuli, which is created by a sudden bradycardic state produced by the DVC. However, where reptiles tend to stay in this state when freezing from threat or waiting for prey to get close enough to attack, a mammal’s VVC quickly inhibits the DVC branch, given the Jacksonian principle (Porges 1995). This enables quick orientation changes typical of the vagal brake, as well as facial and vocalization responses distinctive of the VVC, allowing mammals to have a larger repertoire of actions to take when engaging with novel stimuli (Porges 1995).

Conclusion

Many phylogenetic insights from the theory have led to the idea that a need for more complex reactions to novel stimuli puts an emphasis on greater metabolic oxygen demands as the driving force behind the evolution of the VVC system (Porges 1995). However, numerous psychological and clinical disorders may be a function of

improper DVC and/or VVC activity (Porges 2007). Disorders such as sudden infant death syndrome and sleep apnea may be caused from overactive DVC or an underactive VVC. Disorders that compromise social behaviors, such as autism, may be facilitated by an underactive vagal brake, causing less social regulation and self-soothing behaviors. Other psychophysiological disorders, such as anxiety, may be mediated by overactive neuroception, causing otherwise safe environments to be assessed as threatening, leading to fight, flight, or freezing behaviors.

Pooh-Pooh

Demetra Themistocleous and Xenia Anastassiou-Hadjicharalambous

University of Nicosia, Nicosia, Cyprus

Synonyms

[Expressions of emotions theory](#); [Expressive theory](#); [The interjectionist theory](#)

Definition

The *pooh-pooh theory* suggests that language has emerged from intuitive emotional cries, expressive, for example, of agony or joy.

Introduction

This early speculative language theory refers to the notion that language emerged from unintentional vocal responses to agony, fright, astonishment, enthusiasm, satisfaction, or other emotions (Barber 1965). Although animals produce sounds as well, yet language is unique only to humans. “Ouch!”, “Aaah!”, and “Wow!” are some examples of the unintentional vocal responses emerged from this hypothesis. This theory can be found in the literature as *the expressive theory*, *the interjectionist theory*, or *the expressions of emotions theory* (Barber 1965). Max Muller supported the pooh-pooh theory for a while, but later he abandoned it (Müller 1877).

The notion of the pooh-pooh theory that language has many emotional exclamations has been widely criticized by many reviewers. It has been argued that the explanations provided by this theory constitute a very limited part of the vocabulary of different languages. Further, the various languages worldwide have different interjections. For instance, in English pain is *ouch*, while in Greek it is *aou*. Therefore, it is indicated that

sounds could have been different if their origin was from interjections.

Conclusion

According to the *pooh-pooh theory*, the origin of language emerged from the sounds of our ancestors when they reacted to different emotional states or reactions. The cries and other vocal responses to pain, fright, astonishment, enthusiasm, satisfaction, and other emotions are considered to be the roots of speech. The interjections were of paramount importance to the beginning of communication through speech. To conclude, although early human beings could use words based on interjections, these may have been ultimately overruled by more sophisticated and abstract terms (Mandavilli 2016). Finally, it is important to emphasize that although animals react to the sudden feelings they experience using sounds, they didn't develop language as human beings did.

Synonyms

High status; Peer acceptance; Social dominance; Well-liked

Definition

Children or adolescents who are well-liked and/or admired by their peers.

Introduction

Status in the peer group is a central concept to be addressed when studying children and youth. Specifically, it is important to consider the distinction between a dyadic friendship and the greater overall acceptance of the broader peer group. A common method used to determine peer status is to ask children how much they like or dislike children in his/her class and then use this information to calculate an individual's sociometric status (or peer acceptance, in essence, how much they are liked or disliked by their peers as a whole). One of the groups children can be classified into is "popular children," and research has discussed this group in two categories. First, sociometric popularity is conceptualized by how liked an individual is by their peers and is generally associated with prosocial behaviors, whereas perceived popularity is often associated with social dominance and aggression, and not with prosociality. Children and adolescents who are high in sociometric popularity are viewed positively or liked by many peers, while being viewed negatively or disliked by few. Further, these children tend to have many positive characteristics

that contribute to well-adjusted development and positive experiences. They are generally nominated by their peers and the adults in their lives as being cooperative, sociable, and friendly. Children high in sociometric popularity are generally able to regulate their emotions well and have a substantial number of reciprocal friendships (Litwack et al. 2012). Research has demonstrated that there may be differences between children and youth who are high in sociometric popularity (i.e., well-liked) versus those who are high in perceived popularity (an individual's dominance within the social hierarchy). For example, whereas children who are high in sociometric popularity generally exhibit prosocial characteristics, it may be the case that children or youth who have high levels of perceived popularity may have similar prosocial traits, but may also display some negative traits and engage in antisocial behavior (Cillessen and Rose 2005). These individuals may choose to use both prosocial and coercive (e.g., aggressive) strategies to gain and/or maintain social status and power within the peer group.

Social Dominance: Aggression and Victimization

Children who choose to use aggression instrumentally to achieve their goals tend to be perceived as more popular than children who choose to use their aggression in a reckless fashion (Hawley 2003). From an adaptive perspective, gaining status can provide advantages to the individuals involved including higher levels of reputation or higher quality mates. Research demonstrates that early adolescents with high levels of perceived popularity are more likely to engage in bullying aggression, especially those with low levels of peer acceptance (de Bruyn et al. 2010). Although these adolescents may be disliked for their involvement in bullying aggression, it seems that engaging in these behaviors can provide certain benefits, including higher social status (Volk et al. 2014). This supports theories of evolutionary psychology, which suggest that bullying aggression may be an evolved adaptation and provides evolutionary advantages

to those who engage in the behavior. Specifically, adolescents may use bullying as a strategy to acquire certain benefits, such as social status, greater access to dating and sexual partners, material resources, and social dominance (Volk et al. 2014). Furthermore, longitudinal research demonstrates how popular adolescents are more likely to engage in future relational aggression, which allows them to maintain their high social status (Cillessen and Mayeux 2004). That is, these individuals are more likely to engage in aggression consisting of damaging another person's social relationships or social status, as this type of aggression is generally more effective when used by those already in a position of power.

Although popular adolescents are more likely than their less popular peers to engage in bullying aggression, there is also a small body of literature indicating that popular adolescents are at risk for victimization, specifically by reputational aggression (de Bruyn et al. 2010). High status peers tend to have admirable qualities and influence over their peers which may evoke envy by their lower status peers. Victimization of popular adolescents may arise from competition and rivalry. Reputational aggression consists of spreading rumors and gossip with the intention of ruining an individual's reputation. By derogating the reputation of a high-status peer, adolescents with lower social status have the opportunity to diminish the status of their target and ascend the social hierarchy themselves. Targeting peers with high status and power can be risky for the aggressor if their identity is revealed. Reputational aggression can be covert and anonymous which decreases the aggressor's risk of identification and subsequent retaliation. Popular adolescents who are characterized by aggressive behavior and low peer acceptance are at greater risk of victimization, suggesting that aggressors victimize high-status peers in the form of retaliation or perhaps they are being strategic in selecting their targets (de Bruyn et al. 2010). Targeting popular adolescents with low peer acceptance is a strategic move for the aggressor because these adolescents are less likely to have friends to protect them, and the

aggressor may even receive social approval by selecting an individual who is disliked by the peer group. In fact, research by Spadafora et al. (2018) found that adolescents were less likely to intervene in a bullying situation when they felt as though it may decrease his/her popularity, and more likely to intervene when they thought it could help them to gain popularity.

Risk-Taking Behaviors

During late childhood and adolescence, risk-taking behaviors seem more desirable as they are perceived to bridge the gap from adolescence to adulthood. At this stage, youth start to spend more time unsupervised by their parents and become more involved with their peers. The pressure to conform to peer norms and risk-taking behaviors becomes more common as adolescents feel the need to identify with peer groups (Steinberg and Monahan 2007). Popular individuals may feel this pressure at a greater level to maintain their social status and, therefore, are more likely to engage in risk-taking behaviors. Research has demonstrated that adolescents with greater levels of popularity are more likely to engage in risky behaviors, such as cigarette use, marijuana use, and risky sexual behavior (Prinstein et al. 2011). This greater involvement in risk-taking behaviors may be attributed to a stronger need to conform to peer norms to maintain social status; however, it may also suggest that popular adolescents have greater opportunities to engage in these behaviors. For example, popular individuals have a greater number of dating and sexual partners and are also invited to parties where substance use is common and easily accessible. The involvement of risky behaviors by popular peers is especially problematic because of the high level of influence these individuals have among their peers. Children and adolescents admire the attention that their popular peers receive and will emulate their behavior and preferences with the hope of receiving the same social approval from their peers. Despite the potential risk of greater involvement in risk-taking behaviors, there are also multiple potential benefits.

Positive Outcomes for Popular Children

Popularity in children has been associated with positive outcomes, such as academic competence, friendship quality, and psychosocial adjustment (Chen et al. 1997; Litwack et al. 2012). In regard to academics, research has found differences between popular and average children. In general, classmates tend to nominate popular students as being good students and are perceived by teachers to be more helpful than other students. Further, research supports a reciprocal relationship between academic achievement and peer acceptance, that is, while academic achievement may predict peer acceptance, children's adjustment (including their peer acceptance) is also significantly associated with their academic achievement (Chen et al. 1997). This highlights the importance of the positive adjustment and peer acceptance of children for strong academic achievement.

Moreover, children who are deemed as socio-metrically popular have more friendships with higher levels of intimacy and lower levels of conflict, compared to their rejected counterparts. This is likely due to having larger social network with higher levels of acceptance that allows for greater opportunities to build and develop friendships. Further, youth who have higher levels of perceived popularity, in general, had higher levels of friendship support and a greater number of friends than youth who were nominated as unpopular (Litwack et al. 2012). Lastly, higher levels of popularity have also found to be associated with higher levels of self-esteem and lower depressive affect, again highlighting some of the positive effects for popular children (Litwack et al. 2012).

Conclusion

Overall, it is important to consider children who are characterized as popular may have many positive attributes. Research has shown that these children not only feel more supported by their peers but may do better in school and have better overall psychosocial adjustment (Chen et al.

1997; Litwack et al. 2012). Moreover, having low levels of sociometric popularity has been found to predict depressive symptoms in early adolescence, further highlighting the importance of having status in the social hierarchy (Nolan et al. 2003). Since research also demonstrates negative associations with popularity, it is increasingly important for professionals working with children and youth to understand the importance of popularity and support these students to gain status through prosocial means. For example, Ellis et al. (2016) discuss the “meaningful roles” intervention, which focuses on giving youth alternate prosocial means to increase his/her status within the peer group, such as classroom roles and responsibilities reinforced by peers, to allow them to maintain status instead of resorting to antisocial methods, such as aggression.

Population Bottleneck

Kian Betancourt¹ and Brittany Mabie²

¹Hofstra University, Hempstead, NY, USA

²State University of New York, New Paltz, NY, USA

Synonyms

[Catastrophe](#); [Mass extinction](#)

Definition

An event that drastically reduces the size of a given population.

Introduction

Population bottleneck is the result of a catastrophic event that reduces the size of a population. The kind of event it is can vary considerably, and it can take many different forms as well. These can be climate or weather related (volcanos, earthquakes, hurricanes), things such as genocide (the Holocaust, genocide of Native Americans), biological destruction (the Black Plague), or even environmental destruction such as the deforestation of the Amazon. Essentially, any event that considerably reduces the size of a population of a living creature is considered to be a population bottleneck.

Population Bottleneck with Respect to Climate Fluctuations

Although population bottleneck results in the drastic reduction of a given population, there are times that the bottleneck can be advantageous. For instance, in the case of our ancestors in early hominids, they were likely pushed out of trees and onto the ground due to climate fluctuations (Hawks et al. 2000). With these climate fluctuations came many of these early hominids migrating from the tops of the trees onto the forest floor and begin changing their behavior to adapt to hunting and surviving in their new environment, as well as eventually the African grasslands. However, the vast majority of these early hominids did not make the transition to the forest floor, and likely decided to stay in the trees as they had done all of their lives. Given the nature of the climate fluctuations, staying in the trees was likely disadvantageous given the lack of vegetation and resources to be found. Without these resources, the organisms would die. Thus, it is most likely that the vast majority of these hominids died off and resulted in a population bottleneck, with a very small amount of the population being able

to actually adapt and survive on the ground floor. Of these that did survive, however, would have reproduced to have children adapt to the same lifestyle, and slowly build the population back up to reasonable proportions (Nei et al. 1975). When the population was large enough, the hominids began to migrate out of the forest and into the local grasslands that were also likely due to environmental change and deforestation. Those that were unable to survive on the African savannah did not, and failed to pass on their genes to their offspring due to either being hunted, being unable to survive and find resources, or being unable to find a viable mate in the conditions. Those that did survive were able to successfully adapt and pass on their genes, which long-term led evolutionarily to biological changes and mechanisms that ensured survival and adaptation to their new environment Wall and Przeworski (2000). These changes made what was once a population bottleneck slowly but surely into a flourishing community of hominids that gained skills such as weaponry and communication that their ancestors did not, and would eventually turn into the seven billion people we have on Earth today.

Conclusion

Population bottleneck is a severe decrease in a given population because of a catastrophic event. The name is given because of the shape of a bottle – round and broad at first, representing a large population, to which the “catastrophe” happens at the bottleneck. The population then severely decreases and eventually levels out at a level that was significantly less than its original figure. With respect to human evolution, our early ancestor hominids likely experienced population bottleneck in their transition from trees to the African savannah which most likely came as a result of climate fluctuations.

Pornography and Women's Short-Term Mating

Vincent Barnett
London, UK

Definition

Pornography is conventionally defined as imagery specifically designed to generate sexual arousal, although a related definition is imagery of sex acts themselves. Short-term mating relates to brief sexual encounters such as one-night stands, as opposed to stable long-term mating (pair bonding, either monogamous or polyandrous).

Introduction

It is a widely held misconception that the main function of pornography is to facilitate masturbation. In fact, the main function of pornography is to activate the pleasure circuitry of the brain that is naturally stimulated by sexual interactions in the

real world. This may or may not involve masturbation in any instance of porn usage. Examples of non-masturbatory usage are couples using it as part of their normal sexual activities and individuals viewing it in the same way that they watch non-porn content.

In making the benign suggestion that pornography has evolved, this could be meant in two senses. It could mean how pornography has developed over time, i.e., how the content of pornography has changed in response to cultural and technological trends. However, the evolution of pornography could also be meant in a Darwinian sense, that either pornography is in itself an adaptation or has evolved to fulfill an adaptive function or that the need/capacity for it has evolved by processes of natural/sexual selection: these are more controversial suggestions. The wider notion that narrative storytelling ability serves an adaptive function has previously been outlined (Tooby and Cosmides 2001).

Although it has not been highlighted, Charles Darwin explicitly placed pornography within his evolutionary framework for understanding the origin of animal instincts. While discussing the universal fact that human beings from across the globe have practiced various forms of artistic adornment for a very long period of time, he extended this to include the “almost universal habits of dancing, masquerading, and making rude pictures” (Darwin 1874 [1871], 577). If Darwin thought of “making rude pictures” as a type of artistic adornment, then their potential evolutionary function becomes evident.

Opposition to Pornography

Pornography is one of the most controversial areas of cultural production, eliciting strong feelings both in favor of it and against it, although some people are indifferent to it. Many but by no means all of the strong opponents of pornography are women, for example, the anti-porn radical feminists, but there is also a vocal group of female sex-positive pro-pornography activists. At the heart of the anti-porn attitude is the proposition that porn is exploitative, either of women in general or of the women who are involved in it as performers.

However, the fact that members of the anti-porn grouping only more rarely make the argument that porn also exploits the men that are involved, or that gay porn is exploitative, indicates that sex differences (and the associated evolved psychological mechanisms) are a key component of the controversy over the morality of porn. The contrast is highlighted by the fact that most (if not all) anti-porn advocates argue that pornography exploits women, some argue that porn exploits both the women and the men involved, but nobody has ever argued that porn exploits only the men involved but not the women. This latter argument seems absurd, but it is logically equivalent to stating that porn exploits only the women involved, indicating that there is something unequal at work when judging male versus female involvement in pornography.

A good summary of the calculative logic often at work when women choose to participate in pornography as a career has been provided by the editor of *Razzle* (a UK soft-core porn magazine):

Our would-be [nude] models weren't all desperate. Some of them ... were as bright as canaries, a-twitter with all kinds of daydreams [of fame]. Suzy, for instance. She had no CSEs [UK school exam qualifications], but God had compensated by blessing her with blonde curls, blue eyes and impossibly pointed tits ... She had it [all] planned. *Fiesta* [UK] today, *Penthouse* [UK] next month, and Hollywood [California] next year. (Whittaker 1997, 71)

A survey of US pornography actors/actresses revealed various different motivations for entering the porn industry, including the obvious ones – money, sex, and Suzy's shot at fame – but some less obvious ones too: work flexibility, freedom, and independence, sociability and interpersonal networking opportunities, and mobility across various branches of the sex industry (Abbot 2000, 19–31).

Short-Term Mating

As has been explained in the literature on evolutionary psychology:

In primates, short-term mating occurs in several of the prosimians (e.g., the ring-tailed lemur, *Lemur catta*), New World monkeys (e.g., the squirrel monkey, *Saimiri sciureus*), Old World monkeys (e.g., the rhesus monkey, *Macaca mulatta*), and great apes (e.g., the common chimpanzee, *Pan troglodytes*) ... numerous findings indicate humans are designed for at least some short-term mating. (Schmitt 2005, 264)

It is fairly uncontroversial to state that human females do engage in some degree of short-term mating, the evidence in part being the comparative degree of sexual dimorphism exhibited by *Homo sapiens* compared to other primates and other evolved behaviors such as the expression of jealousy and the prevalence of infidelity (Ibid., 260), but understanding the reasons why they do so is more controversial.

The most obvious reason – simply for pleasure – might sometimes apply, but there are a number of other potential explanations that have been advanced in the literature. These are, in exchange for resources, to obtain better/more diverse genes, to switch mates, to acquire mating skills, and to manipulate mates (Buss 2004, 176; Schmitt 2005). It seems likely that women may engage in short-term mating for a number of reasons in combination.

The hypothesis that ancestral women engaged in short-term mating in exchange for goods or other services is common in the evolutionary psychology literature, but it is more controversial outside of it. For example, some radical feminists have questioned this notion, claiming that it serves to legitimize contemporary prostitution. The link to pornography is less frequently considered, but the argument is similar: women have evolved psychological mechanisms relating to behavior exchanging sex (or pornographic imagery of sexual activity) for other goods, thereby allowing sex (and porn) to be conceived of as a service offered by them to men. This service can be in the form of exchange for money (prostitution and pornography) or other items (e.g., meals).

One problem with the radical feminist opposition to both prostitution and pornography is that the women involved often state that they are exercising their own free will in choosing to become pornography actresses, and they resent

anyone suggesting that they have been brainwashed into doing it. It is true that some pornography actresses later came to regret it, a classic case being Linda Boreman (a.k.a. Linda Lovelace) who starred in the 1972 film *Deep Throat* (Barnett 2018), but many other women have remained supportive of their career choice. Toward the end of Boreman's life, she worked in pornography again after previously rejecting it as exploitative. She then declared that some feminists had exploited her name in their publications on her pornography experiences: a case of all exploiters are equal, but some are more equal than others.

Two Human Natures

It seems reasonable to suggest that the different attitudes exhibited by some to female against male participation in pornography in part stems from the different evolved psychologies of men and women (Davies and Shackelford 2008; Salmon 2008). It is usually assumed that men will enjoy any and all short-term mating opportunities (e.g., porn sex, drunken night-club sex), but there is an implied assumption made by some that women will not, or at least not in the same quantity or to the same degree.

Reading through the memoir literature written by female porn stars leads to the conclusion that they do not enjoy some significant portion of the porn sex, but on some occasions, they do enjoy it very much (Jameson 2004). Compare this with the situation of female lavatory cleaners, who probably never or only very rarely actually enjoy the work of cleaning toilets as work.

Moreover, the proliferation of Internet porn has produced examples of female porn stars that only (or mainly) have heterosexual porn sex with their real-life male partners while also participating in other types of sex scene which do not involve other men, such as solo masturbation. For example, the Czech pornography actress Hedvika Makošová (a.k.a. Victoria Sweet) has performed in solo masturbation scenes, girl-girl scenes,

female-only water sports, and also straight and oral sex with her boyfriend.

In such cases the percentage of porn sex that female participants can be said to enjoy probably increases greatly, especially when it is recognized that many female porn stars identify as bisexual. It would be difficult to argue that a female lavatory cleaner has a better work experience than a partner-only bisexual porn star, especially when the comparative pay rates are included in the analysis.

Cleaners usually earn the minimum wage (around \$10 per h); female porn stars can earn up to \$1,000 for a 1-h scene, depending on the type of sex that is involved. In comparative terms, it would be difficult to maintain that the porn star's job is 100 times less fulfilling than the toilet cleaner's job, and therefore the comparative pay rates are commensurate with the nature of the work. It is true that the working life of porn stars is much shorter than that of cleaners, but the former can embark on new careers after leaving porn.

Conclusion

A key feature of pornography not often considered by feminists is that the women involved invariably receive much higher pay rates than the men involved in acting in the same scene. One position could be that this constitutes discrimination against men, but this argument is absent from the literature on pornography.

From an evolutionary perspective, pornography is just one variant of the long history of females employing their sexual capacity to obtain resources from males, as an extension of the short-term mating strategy deployed across various primate species. The different pay scale for male against female porn stars just reflects the fact that the males involved in porn are receiving part of their payment as sex, as against the women, who do not conceive of men having sex with them as any type of payment. This constitutes a classic example of the naturally evolved phenomenon of "two human natures."

For radical feminists, this sex-for-resources process is exploitative, but most other *Homo sapiens* accept it as a natural part of life as it has evolved on planet earth over millions of years. It is logically possible to conceive of a primate species evolving that exhibits different behavioral logic in this regard, for example, where females pay males for sex. Among contemporary *Homo sapiens*, male gigolos are not unknown, but these gigolos are rarely considered as objects for study in the literature on prostitution, which usually focuses only on female prostitutes and their male clients.

Pornography as a Human Product and Source of Data

Mark Huppin and Neil M. Malamuth
University of California, Los Angeles, CA, USA

Synonyms

[Erotica](#); [Sexually explicit material](#)

Definition

Sexually explicit material primarily intended to sexually arouse the consumer.

Introduction

Evolutionary psychology (EP) contends that how people respond to current environmental stimuli is shaped by mental mechanisms that evolved in response to problems faced by our ancestors. EP perspectives seek to identify ultimate causes of behavior, complementing the focus on proximate causes characteristic of other psychological theorizing. By examining within the framework of evolutionary theories how people use pornography and differences between men and women in their consumption preferences, EP researchers have tested unique predictions and gained important insights about the evolved mechanisms of consumers.

Pornography refers to sexually explicit material primarily intended to sexually arouse the consumer. Such content is distinguished from a large proliferation of sexual material around this core in which continuous sexual stimulation and consequent arousal are not the primary motivation, such as movies in which some of the scenes include references to or actual portrayals of sexual interactions. It is clear that use of pornography is common and in recent years is primarily accessed on the Internet, a visual medium. For example, in 2015 people watched nearly 4.4 billion hours of

pornography on popular website *Pornhub*, which is the equivalent of spending more than 500,000 years watching online porn (“Pornhub’s 2015 year in review,” 2016).

Pornography and Environmental Mismatch

Put simply, EP theories on pornography suggest that it can be understood as the “parasitizing” of evolved mechanisms for sexual responses, particularly reflective of short-term sexual mating strategies. These mechanisms evolved to cause attraction and arousal to potential sexual mates. In ancestral environments, such attraction and arousal would have increased the likelihood of engaging in sexual acts contributing to reproductive success. Pornography use can activate the same evolved mechanisms for sexual responses. However, in current environments the activation of such evolved mechanisms in the context of pornography use does not typically lead to greater reproductive benefits. Indeed, although pornography may sometimes be used to stimulate sexual intercourse potentially resulting in reproduction, it typically elicits behaviors without clear reproductive consequences, namely, masturbation. The elicitation of such behaviors is due to a mismatch between modern and ancestral environments. Mismatch in this context indicates that a behavioral response that may have been adaptive in evolutionary environments and therefore became part of humans’ psychological mechanisms may not contribute to reproductive success in current environments.

From an EP standpoint, we are mechanism activators, not fitness strivers. Consider taste buds for sweetness, which evolved in ancestral environments as a way to increase the likelihood that we would eat scarce nutritious substances, for example, ripe fruit. Unfortunately, these taste buds respond as strongly or even more so to processed, artificially created sweets lacking in nutritional value, which were designed by modern technology to similarly activate our sweetness mechanisms. In a modern environment populated with an overabundance of such artificial sweets,

consuming them may be pleasurable because of the parasitizing of psychological mechanisms designed to discriminate between ripe fruit and other, less nutritious foods, even though in current environments the elicited behavior of eating may actually be harmful rather than beneficial to our health. In the same way, current use of pornography parasitizes an evolved tendency to become aroused by those sexually explicit stimuli that would appear to have had adaptive significance, despite the fact that such use may result in repeated behaviors, particularly masturbation, that may actually lessen the probability of reproductive success.

Evolutionary psychology’s unique contribution to understanding of and learning from the very wide use of pornography may be illustrated in three areas: (1) Content of Pornography Appealing Primarily to Men, (2) Content of Pornography Appealing to Women, and (3) Content Specifically Related to Increasing Reproductive Success.

Content of Pornography Appealing Primarily to Men

Importantly, by providing a window to our evolved psychological mechanisms, applying the EP paradigm can provide a framework for understanding gender differences in pornography consumption. According to sexual strategies theory (Buss and Schmitt 1993), the adaptive mating problems faced by ancestral men and women when pursuing long-term or short-term mating strategies differed in important ways. Those males who evolved mechanisms that increased their sexual mating with a larger number of fertile, sexually accessible women were more likely to become our ancestors who, in turn, transmitted such evolved mechanisms to subsequent generations of male offspring. Conversely, for those women who were equally attracted to short-term relationships involving copulations, more dire consequences would have ensued. Such a tendency would have “undermined female choice of partners and the circumstances of conception, reduced the likelihood of acquiring male parental

investment, increased the likelihood of being beaten, abandoned, or killed by a jealous husband (and also by angry brothers), and drastically impaired female fitness” (Ellis and Symons 1990, p. 457). Women today consequently are relatively selective about short-term partners, and when such mating does occur, they are particularly attracted to characteristics associated with “good genes” that in ancestral environments would have conferred competitive advantages for their offspring.

From an EP perspective, most pornography can be seen to conform to men’s rather than women’s short-term mating psychology or sexual fantasies. Indeed, much of it fits well with “solving” the main problems or challenges encountered by men over evolutionary time when pursuing short-term mating designed to produce the most offspring: identifying women who are willing to engage in casual sexual acts without a long-term commitment and who display a number of cues associated with reproductive fitness, such as young age, clear skin, good muscle tone, and facial symmetry. Studies show that men prefer content consistent with such a strategy for successful short-term mating, including female pornography actors with the ideal characteristics for reproductive success, pornography featuring many different women rather than the same women performing different sexual acts, and pornography devoid of any emotional attachments or nuances associated with encumbering commitments (Malamuth 1996).

Also consistent with EP theory, after viewing sexually explicit videos, men experience less negative affect than women do, which from an EP framework is associated with female hesitation to engage in unbridled sexual acts (Malamuth 1996). Furthermore, compared to women, men are generally more sexually aroused by pornography and are much more likely to use pornography on a regular basis as a masturbatory tool, whereas women are more likely to use pornography sporadically and seek it out primarily out of relatively fleeting curiosity (Hald and Malamuth 2008). All this helps to explain why men represent the greatest proportion of pornography viewers worldwide (e.g., 76% in 2015 according to

Pornhub’s latest statistics; in no country are women the majority of viewers; “Pornhub’s 2015 year in review,” 2016).

It is essential to note, however, that our psychological mechanisms are the result of an interactive blend of nature and nurture. They process and respond to the information from our social and physical environments and do not elicit rigid, fixed behaviors. Illustratively, a recent study of European Union countries found that while there are still considerable differences in many respects (Hald and Malamuth 2008), gender differences in the use of pornography are less pronounced in more liberal countries (Ševčíková et al. 2014).

Content of Pornography Appealing to Women

In contrast to male-oriented pornography, what does elicit more uniformly positive affect from women is erotic material that specifically targets women’s evolutionary psychological susceptibilities by conforming to the adaptive problems faced by our female ancestors. One example of this has been romance novels, which are written almost entirely for women and have been called a type of woman’s pornography. A heroine overcoming obstacles to secure a ruggedly handsome, physically imposing, intellectually gifted, often “dangerous” man who eventually desires and loves only her characterizes these works. Because the male character featured in these works is not only of high genetic quality but also, by the story’s end, turns kind and loving toward the heroine, romance novels may provide the best of both worlds in terms of women’s mating preferences. As Salmon and Symons (2004, p. 96) concluded, “We believe that genre romances are analogous to male-oriented porn in the sense that they are wish-fulfilling fantasies, well designed to pick the locks of the pleasure circuits in female brains. . .”

In addition to its descriptive power, evolutionary theory can help generate novel, testable predictions. For instance, Salmon and Symons (2004) have studied slash fiction, a brand of erotic fiction in which the lovers are both male. Slash fiction is typically very sexually explicit, although

the emphasis is on the emotional rather than physical elements of sex. They are essentially love stories, written primarily by and for women, in which the male characters suddenly find that they love one another. In their examination of slash fiction, these researchers asked who chooses to read or write such works. Two possibilities exist: (1) slash fiction should appeal to only a subset of psychosexually unusual women, or (2) it should appeal more broadly to mainstream romance novel readers. In view of the strong thematic correspondence between slash fiction and romance novels, they predicted the latter result. A study of members of a "romance readers club," in which 78% of members reported enjoying a slash fiction novel at least as much as other romances, generally supported their hypothesis (although there is some evidence that the female mating psychology of slash readers is a "little masculinized," as indexed, e.g., by reported tomboyism and frequency of fantasizing about sex with someone other than a current partner).

Content Specifically Related to Increasing Reproductive Success

Another example of using evolutionary psychology to inform predictions about pornography preferences comes from sperm competition theory. Sperm competition occurs when the female of a socially monogamous species engages in extra-pair copulations, resulting in some extra-pair fertilizations. To the extent that sperm competition was an important selection pressure for ancestral males, men may have evolved adaptations designed to reduce the risk of cuckoldry associated with female sexual infidelity. In fact, men at greater sperm competition risk do appear to possess indicators of adaptive mechanisms. One element of this concerns the role of sexual arousal responses. Greater sexual arousal to cues of sperm competition would have been a valuable strategy for dealing with paternity uncertainty by helping to elicit immediate copulation. This has led to the prediction that men should be more aroused by and prefer to view pornography that evokes the presence of male rivals. In support, researchers

have found that men often do prefer pornography depicting multiple males and a single female (MMF). For example, for pornographic DVDs, the frequency of scenes on the DVD covers showing two men interacting with one woman (i.e., simulating conditions of sperm competition) predicts the sales rank of the DVD, whereas this is not the case for covers depicting two or more women relating to one man (McKibbin et al. 2013). Others have discovered that for pornographic videos, photographs, and stories, men prefer MMF scene/image contents to other types of pornographic scenarios (Pound 2002). Relatedly, men have been found to produce a higher percentage of competitive (i.e., motile) sperm from viewing pornographic images of two men and one woman than from viewing depictions of three women. Higher ejaculate quality increases the likelihood of fertilization during intercourse (for a summary of these findings, see Pham and Shackelford 2015). These data taken together suggest that when men use MMF pornography, it is for its special arousal-inducing properties, which may in turn be the product of adaptations to sperm competition.

Conclusion

EP perspectives have provided unique and well-supported insights and predictions on the selection and use of pornography, which constitutes a large segment of the world's media. Scholars seeking to provide a comprehensive understanding of such topics as gender differences in the type of pornography consumed and the frequency of usage across cultures may include proximate factors including adherence to gender stereotypes and norms, but such explanations are complemented by incorporating knowledge about evolved mating strategies. In generating predictions specifically linked to reproductive success in ancestral environments, EP researchers have provided examples of how modern behaviors that appear at first glance to be contradictory to an evolutionary framework (e.g., males engaging in relatively frequent masturbatory behavior that has no clear reproductive benefits) are

actually highly supportive of evolutionary theory. Moreover, findings regarding sperm motility would not have been generated by any theory that only relies on proximate factors. Although the amount of currently available research on pornography derived from EP theories is not extensive, future work focusing on this controversial topic may benefit considerably from incorporating unique insights and predictions that may be derived from EP theories.

Positive and Negative Reinforcement and Punishment

University of Nicosia, Nicosia, Cyprus

Synonyms

[Consequences](#); [Contingencies](#); [Operant conditioning](#); [Punishment I](#); [Punishment II](#); [Reward](#)

Definition

Consequences of behavior in operant conditioning that result in strengthening (reinforcement) or weakening (punishment) the frequency of that behavior.

Introduction

During the operant conditioning process, the consequences of behavior affect the probability of future demonstrations of that behavior. Thorndike (1898, 1911) and Skinner (1938) have shown that reinforcement (also known as reward) strengthens a behavior, i.e., increases its frequency, whereas punishment weakens a behavior, i.e., decreases its frequency. Reinforcement can also be distinguished as primary/secondary and intrinsic/extrinsic.

Positive and Negative Reinforcement

Reinforcement is an environmental stimulus whose presentation results in the strengthening (increase of the frequency) of an exhibited behavior. An organism, after a number of contiguous presentations of behavior-reward, associates a specific behavioral action with a desired outcome and is motivated to repeat it in the future. Reinforcement can be positive or negative. When pleasant consequences occur, the reinforcement is described as positive. When aversive consequences are removed, negative reinforcement takes place. Positive Reinforcement involves the presentation of a stimulus that increases the occurrence of a behavior (e.g., receiving food after pressing a lever in a Skinner box). Negative Reinforcement results in an increase of the frequency of a behavior because it results in the removal of an unpleasant stimulus (e.g., a person puts on their seat belt immediately upon entering the car, to stop the annoying sound of the buzzer).

Primary and Secondary Reinforcement

Primary reinforcers have the capacity to innately reinforce behavior (Powell et al. 2017), and they are sometimes also called unconditioned reinforcers. They satisfy a built-in, biology-related need or desire (e.g., food, water, oxygen, sexual contact), require no previous learning, and they are essential for our physiological and psychological well-being.

Secondary reinforcers, also known as conditioned reinforcers, are previously neutral stimuli that have become reinforcing through repeated association with another reinforcer (e.g., praise, good grades, money) (Powell et al. 2017). They become reinforcing through the process of classical conditioning, and they are not essential for physiological well-being. Positive experiences with these events serve as effective reinforcers that guide present behavior.

Intrinsic and Extrinsic Reinforcement

Reinforcement can be intrinsic if the act of performing the behavior is pleasant in itself for the organism. Early research has shown that monkeys engaged in solving mechanical puzzles (Harlow et al. 1950) without the need for additional incentives. In human learning, feelings of success, competence, and pride are intrinsically reinforcing (Ormrod 2016). Extrinsic reinforcement is reinforcement received by consequences external to the behavior. They may include material reinforcers (money, actual objects such as food or toys), social reinforcers (gestures received by others to communicate positive regard, such as a smile, attention, praise), activity reinforcers (engaging in a personally pleasurable activity such as watching TV or playing a favorite game), and positive feedback (positive messages about progress of learning such as grades). It has been argued in several studies that when extrinsic reinforcement is given for intrinsically motivating activities, this can decrease intrinsic interest (Deci and Ryan 1985; Lepper et al. 1973; Akin-Little et al. 2004; Deci et al. 1999, 2001). Dickinson (1989) claimed that this effect is transient and that it is less likely to occur if the extrinsic rewards are reinforcing, noncompetitive, based on rational performance standards, and when there is repetitive delivery of the reinforcers. Some meta-analyses (e.g., Cameron and Pierce 1994) have disputed the above and showed that extrinsic reinforcement has little or no effect on intrinsic motivation, although they acknowledged that external rewards can possibly undermine intrinsic motivation under certain conditions such as when the reward is expected, tangible and given only for the act of performing an activity.

Positive and Negative Punishment

Punishment results in a decrease in frequency of a particular behavior because it is associated with an unpleasant outcome (Powell et al. 2017). In positive punishment (also known as punishment I), a particular behavior is followed by a presentation of an unpleasant stimulus (e.g., a verbal reprimand

after a child breaks a vase). In negative punishment (also known as punishment II), a pleasant stimulus is removed (a child is not allowed to watch TV because they have not completed their homework). Various problems have been identified with the use of punishment, and it should be used very cautiously as it may elicit strong emotional responses, aggression, avoidance behavior, and resorting in the use of punishment to modify others' behavior through the processes of modeling (Powell et al. 2017).

Conclusion

In behavioral learning theory under the paradigm of operant conditioning, the consequences of behavior serve as guidance for future behavior. When behavior is followed by pleasurable consequences, reinforcement occurs and the behavior is strengthened in the future. When behavior is followed by aversive consequences, punishment occurs and the behavior is weakened. Reinforcement and punishment are further distinguished by whether a stimulus is added (resulting in positive reinforcement and positive punishment) or removed (resulting in negative reinforcement and negative punishment). Other identified forms of reinforcement include primary/secondary reinforcement and intrinsic/extrinsic reinforcement.

Synonyms

Healthy sexual development; Normal sexual development

Definitions

It is an adaptive, harmonious, and healthy development of sexuality.

Introduction

Development of humans is an ever evolving process. Sexuality is an essential element in the life of a human being. Its importance is not limited to procreation and survival of human race; rather it has many other significant roles. Sexuality adds to the identity of an individual. Sexuality needs to be understood beyond the boundaries of

health, as sexuality is also a social, cultural, economic, ethical, legal as well as spiritual phenomenon (Diamond 2014).

Development of sexuality can be understood from the aspects of physical, emotional, cognitive as well as social domains (Scott and Walsh 2014). Sexual development starts from the intrauterine life and continues throughout the life. Across the lifetime of an individual, many transitions come, during which sexual development gets different contours (Moshman 2014). Adolescence period is one of the major transition during which an individual's sexuality evolves into a mature form, physically as well as psychologically (Kar et al. 2015). Sex is a primitive behavior that serves to meet the basic needs (procreation) to the higher needs (recreation or pleasure) of life (Fig. 1). Sex also has an important function in holding the relation with the partner. Throughout the life time of the individual, a complex interaction between the sexual needs and sexual development goes on. Initiation of sexual activity varies across cultures. Developmental processes influence the thoughts, feelings, behaviors, and attitude towards relationship, other than the physical changes, which in turn direct the sexual activity (Arbeit 2014).

Factors Affecting Sexual Development

Sexual development can be manifested in the form of anatomical, physiological, as well as

Positive Sexual Development, Fig. 1 Spectrum of sexual behavior and factors influencing sexual development

psychological changes. There are various factors that influence the process of sexual development. Broadly they can be categorized as biological (physical), psychological (cognitive and affective), and social factors (Fig. 1).

The sex chromosomes determine the development of gender-specific sex characteristics. Gender-specific hormones facilitate the growth and development of sexual organs as well as gender-specific characteristics. Across the lifespan of an individual, under the influence of gender-specific hormones, development of sexual organs continues. Gender-specific hormones also influence the gender-specific thinking and behavior. Appropriate genetic makeup and neuroendocrinal integrity is responsible for positive sexual development. Similarly, psychological factors like individual's perception and attitude towards own sexuality to sexuality as a whole in broader sense also influence sexual development. Individuals, who perceive sexuality in a distressing and deformed way encounter difficulties in the sexual life. Social factors like parenting, peer relationship, life experiences, cultural values have significant influence in the sexual development (Moshman 2014).

These biological, psychological, and social (sociocultural) factors also influence each other (Halpern 2010). Moshman described development of sexuality as an extended (evolving across the lifespan), self-regulated (beyond the regulation of environment and genes), and qualitative (addition of newness time to time) process that occurs in a progressive fashion (Moshman 2014).

Positive Sexual Development

To be recognized as "positive sexual development," development of sexuality should follow certain norms as below.

1. It should be within the accepted norms (anatomical, physiological, and psychological).
2. It should be in harmony with self, family, and the sociocultural milieu.
3. Experience about sexual activity should be free from guilt and compulsiveness.

4. There should be respect for divergent view points and contrasting opinions about sexuality.
5. One should be able to understand and express one's sexuality appropriately without shame, guilt, and undue inhibitions.
6. One should have the ability to choose one's sexual partner as per mutual understanding without conflict and social bias.

An individual with positive sexual development perceives sex as a biologic function and should be free from myths and misconceptions. The individual should be able to express about sexuality without prejudices and biases. They should adopt safe sexual practices. Individuals with positive sexual development should be adopting socioculturally acceptable sexual behavior without any distress. As per Arbeit, certain skills like sexual selfhood (identity, desire, ethics); sexual empowerment (coping, setting boundaries); and sexual negotiation (consent, protection) help in positive development (Arbeit 2014).

It is also worthy to understand the range of sexual behavior on the basis of sexual preferences (exclusively heterosexual to exclusively homosexual). These ranges of sexual behaviors are in a continuum. An individual with positive sexual development has apparently no distress with own sexual preferences and is adaptable with the society without causing any social distress. But it is a debatable aspect of positive sexual development, as homosexuality is still not accepted as a normal sexual behavior in many cultures.

Implications

Lack of proper sexual development occurs in conditions that result from improper development of genital system (genetic disorders like – Turner syndrome, Fragile-X- syndrome; endocrinal disorders like – Cushing's syndrome, gonadal hormone insufficiency; trauma to the genitalia like - castration, amputation of genitalia; tumors involving the genitalia like - testicular tumor, ovarian tumor; toxic causes that impair gonadal

functioning like - heavy metal poisoning, chronic alcohol use). Sexually transmitted diseases also hamper positive sexual development. Difficulties of gender orientation and identity also produce significant distress.

Positive sexual development has a noticeable bearing on sex education, which needs to be congruent with respect to the sociocultural, moral, and ethical values as well as age appropriate for the individual.

Understanding positive sexual development will help the individual in promoting sexual health and preventing sexual dysfunctions, sexual abuses, teenage pregnancy, sexually transmitted diseases, and sexual conflicts. Better sexual health will obviously add to the betterment in global health.

Conclusion

Positive sexual development provides a positive identity to the individual. It makes an individual sexually acceptable as well as adaptable. An individual with positive sexual development possesses competence, confidence, and better scope for performance.

Definition

Set of studies that investigate the effects of colonization on colonized and colonizing peoples.

Introduction

Postcolonialism refers to a set of studies with an interdisciplinary approach that investigate the impacts of European colonization and imperialism on culture, identity, and knowledge production, among other aspects (Gandhi 1998). The historical marker of the postcolonial perspective is the struggle for the independence of African countries and the development of Indian subaltern studies (Ballestrin 2013). The authors of this approach criticize the dominant currents of knowledge, questioning the Western narrative on modernity that places Europe at the center of the historical, political, economic, and epistemological process. In the last decade, postcolonialism gained strength alongside theories such as poststructuralism, psychoanalysis, deconstructivism, and feminism, as an important critical discourse in the social sciences. The postcolonial intellectual constitution and formation of thought are marked by the influence of Marxism and poststructuralism/postmodernism.

Colonialism and Its Effects

Colonialism was a social, political, and economic phenomenon that consisted of the conquest, exploitation, and aggressive violation (e.g., slavery, genocide) of various peoples in the world by European civilizations, having extended for almost five centuries. To a large extent, the richness of WEIRD countries (Westernized, educated people from industrialized, rich democracies) is directly linked to this historical process. European dominion over the world has established frameworks of relationships between nations and between individuals that remain to this day (Grosfoguel 2016).

There is evidence that the psychological processes associated with colonialism remain long after the colonial relationship ends. Quijano (2005) conceived that coloniality would constitute subjectivities based on colonial parameters with the valorization of whiteness, the male gender, wealth, first world nations, and heterosexuality. As with other collective traumas, the traumatic

effects of colonial practices are passed down through generations. Researchers have been investigating the psychological effects of colonization (e.g., colonial mentality, internalized oppression) on colonized populations, such as a negative view of cultural identity, self-rejection, low self-esteem, and depression (Okazaki et al. 2008).

In addition, false beliefs about European superiority as the legitimate producer of truths and knowledge were created during this period. Thus, Europe was pretentiously placed as the culmination of human cultural evolution due to a premise of sociocultural evolutionism that says that cultures were selected in a manner analogous to biological species, a so-called conception of social Darwinism. Goff et al. (2008), when studying dehumanizing inferences arising from the beliefs of social Darwinism today, have found mental associations between Black people and monkeys to be linked to the biological explanations of racial hierarchies. Such associations affect human judgments by dehumanizing a portion of the population. For example, Black defendants are described in words associated with monkeys more often than White defendants in newspaper reports; and they are the ones who usually receive the most severe penalties in judgments.

Finally, perhaps one of the main points of convergence of postcolonial studies is the dominance over the production of knowledge. Seminal works question the formation of European knowledge within the Enlightenment tradition to the detriment of other possibilities of elaboration of concepts and ideas (e.g., Freire 1972; Martín-Baró 1986; Spivak 1988). For these authors, colonized and colonizers suffer the horrors of imperialism and need to be decolonized. They need to find ways of overcoming the historical relationship of exploitation and domination, not only in political-economic terms but also over their minds and bodies. In the field of knowledge production, they must decolonize knowledge (Grosfoguel 2016). Formerly subaltern peoples must have their voices recognized in their theories, methods, and ways of constructing knowledge, gaining space and thus composing other modernities (Gandhi 1998).

Postcolonialism and Mainstream Psychology

In this European imperialist colonial period, psychological science was influenced by current ideas and was also complicit in the colonizing process generated by scientific racism, which has segregated peoples in many parts of the world. Paulo Freire (1972) and Martín-Baró (1986) wrote about how psychology followed the interests of the powerful, strengthening oppressive and individualizing structures that were, actually, social. In this way, it served as an instrument of rationalization and justification of the oppression and exploitation of native peoples (Gandhi 1998). Evolutionary psychology in particular is criticized for supporting conservative political ideologies, such as economic neoliberalism or the naturalization of gender dichotomies (Pinker 2002). Evolutionary psychology has attempted to conduct multicultural studies in search of understanding human cognitive mechanisms shaped by evolution. The search for these explanations helps to create more accurate and affective intervention models to deal with major human problems, such as racism, inequality, and oppression. Such discoveries can be articulated to construct critical positions that confront the status quo.

Conclusion

In general terms, postcolonialism is an interdisciplinary movement that seeks to understand the effects of colonization. One of the main questions raised is the validity of the knowledge produced by the hegemonic way of thinking and producing knowledge (e.g., supposed scientific neutrality, restricted objectivity), as well as the extrapolation and universalization of the findings to other cultures. Many of the premises and discoveries made by evolutionary psychology in the quest for these universals can be used to question the status quo in society, with emancipatory potential. In addition, postcolonial studies could analyze discursive practices around the knowledge produced by evolutionary psychology and its impacts on everyday practices. These analyses can provide clues to the

relationship between power and subjectivity, as well as pointing out ways of resistance.

Postpartum Depression

Sujita Kumar Kar and Kopal Rohatgi
Department of Psychiatry, King George’s Medical University, Lucknow, UP, India

Synonyms

[Perinatal depression](#); [Peripartum depression](#)

Definition

Depressive episode of postpartum onset.

Introduction

Postpartum depression is one major psychiatric complication associated with child birth, which adversely affect the quality of life of mother as well as significant ones related to the mother. Postpartum depression negatively affects the parenting as well as relationship with the spouse (Moore Simas et al. [2018](#)).

Prevalence of postpartum depression among women ranges between 10% and 15% (Brummelte and Galea [2016](#); Couto et al. [2015](#)). The onset of symptoms in most patients is antepartum (~50%) (American Psychiatric Association [2013](#)). Postpartum depression becomes different from depressive episodes unrelated to childbirth by the heterogeneity in phenomenology of postpartum depression as well as diverse etiological factors attributing to it (Consortium [2015](#)).

Etiopathogenesis of Postpartum Depression

There are multiple causes of postpartum depression. Genetic basis of postpartum depression has been discussed in literature, which covers genetic susceptibility, epigenetic phenomena, as well as genetic polymorphism of mono-amine neurotransmitters; however, the currently available evidences

regarding genetic association with postpartum depression are insufficient (Couto et al. 2015). Many physiological changes occur in pregnancy and in the postpartum period. Perinatal depressive symptoms can be due to a hormonal imbalance involving the hypothalamo-pituitary adrenal axis (HPA axis) and hypothalamo-pituitary gonadal axis (HPG axis) (Brummelte and Galea 2016). This occurs rapidly in the first week after delivery. Women sensitive to rapid changes in the levels of these hormones might be at higher risk of developing postpartum depression (Schiller et al. 2015). These also lead to differential risk by affecting stress response and processing of emotions. A predictor can be elevated midgestational placental CRH. Also, density of monoamine oxidase A in prefrontal and anterior cingulate cortex is increased. Risk factors include firstly and foremost past history of postpartum depression, past history of unipolar depression, past history of anxiety disorder, family history of depression, and ongoing stressful events occurring and continuing through pregnancy and delivery. Along with these, history of sexual abuse, premenstrual dysphoric disorder, postpartum blues, young age (<25 years), single parenthood, marital conflicts, unwanted pregnancy, and birth of a female baby can predispose to the disease (Guintivano et al. 2018a, b). Perinatal anxiety disorders and sleep disturbances occurring during this period can act both as a risk factor and may exist as a comorbidity. Overlaps between the neurotic spectrum disorders are common; thus, sometimes it may be difficult to differentiate between them and take them as separate entities. Apart from these, psychosocial factors may also have a role to play. Socio-economic status, social position, employment status, income, migration, quality of marital relationship, psycho-social support, as well as expectations from pregnancy also considered to have determining role in postpartum depression (Guintivano et al. 2018a; Turkcapar et al. 2015).

Clinical Features of Postpartum Depression

The clinical features of postpartum depression are similar to that of a depressive episode independent

of pregnancy of postpartum (Turkcapar et al. 2015). Women suffering from postpartum depression often present with persistent sadness, lack of energy, and easy fatigability leading to difficulty completing her daily activities and inability to properly care for the infant along with loss of interest in previously pleasurable activities, which is commonly known as anhedonia. In addition to the above features, crying spells, lack of appetite, disturbed sleep, suicidal ideations, hopelessness, impairment of concentration, poor self-care, as well as poor care of the child may present, which significantly affects the quality of life and functioning. The patients may experience psychotic symptoms (e.g., delusions, hallucinations) and may have psychomotor disturbances as well. Risk of infanticide increases, if the mother develops psychotic symptoms during the course of postpartum depression. Women, who experience psychotic symptoms during postpartum depression, are more likely to develop similar symptoms in their subsequent pregnancies. Women suffering from postpartum (peripartum) depression often experience severe anxiety, which sometimes amount to panic attacks (American Psychiatric Association 2013). It is important to differentiate postpartum depression from postpartum blues ("baby blues"), which commonly characterized by repetitive crying spells, disturbed sleep, and weakness developing mostly within 2–3 days postdelivery. These symptoms are usually self-limiting and resolve within 2 weeks, hence, do not require any intervention (Sadock et al. 2015). In case, these symptoms do not resolve within the 2 week time period; a diagnosis of postpartum depression is much suited. Similarly, during postpartum many women report about altered appetite, sleep as well as energy level, which are self-limiting.

Nosological Status of Postpartum Depression

The ICD-10 classification of mental and behavioral disorders: diagnostic criteria for research classifies postpartum depression under "Mild mental and behavioural disorders associated with the puerperium, not elsewhere classified" and

denoted by code F53.0 (World Health Organization 1993). As per ICD -10, the onset of symptoms of depression should be within 6 weeks of childbirth. The Diagnostic and statistical manual of mental disorders (DSM-5) had kept “postpartum onset” as a specifier of the depressive disorder and considers the onset of symptoms within 4 weeks of childbirth (American Psychiatric Association 2013).

Management of Postpartum Depression

Postpartum depression is an undertreated clinical entity (Werner et al. 2015). Women with postpartum depression need to be evaluated in detail for confirmation of the diagnosis and association of co-morbid medical as well as psychiatric conditions. Detailed history taking, serial mental status examinations, physical examination, and appropriate blood investigations might be useful in ascertaining the diagnosis. Females at risk of developing postpartum depression can be screened using the Edinburgh Postnatal Depression Scale (Brockington 2004; Cox and Holden 2003). This can be applied even in pregnant women. Thus, this can form an important basis for diagnosis. Certain medical disorders (hypothyroidism and vitamin B12 deficiency) may increase the risk of postpartum depression, which need to be investigated for, if such suspicion arises. Apart from medical comorbidities occurring with postpartum depression, psychiatric disorders (obsessive compulsive disorder, panic disorder, generalized anxiety disorder and post-traumatic stress disorder) may coexist. Onset of the comorbid psychiatric conditions can be prepartum, antepartum, or postpartum.

The management plan depends on the nature of psychopathology, severity of episode, associated psychosocial stressors, family support, socioeconomic status and affordability, past history, family history, substance use, and response to medication in past (if any). Antidepressants are the mainstay of treatment. Selective serotonin reuptake inhibitors are commonly used antidepressants in the management of postpartum depression. Addition of antipsychotic agents may be required, if psychotic symptoms present during postpartum

depression. Benzodiazepines need to be used cautiously, as per the need. Caution need to be taken during use of psychotropic medications in lactating mothers as these are secreted in breast milk. Electroconvulsive therapy is another safe alternative to the pharmacological treatment. Psychological interventions (cognitive behavior therapy, interpersonal therapy, and supportive psychotherapy) are also found to have beneficial effect in postpartum depression.

Implications of Postpartum Depression

Maternal mental health is important for development of mother-child bonding. Compromised mental health of mother due to postpartum depression results in poor bonding with child and subsequently difficulties in development of social, behavioral, as well as cognitive skills (Brummelte and Galea 2016). Postpartum depression adversely affects the birth outcomes; hence, it is of utmost importance to conduct the mental health evaluation of mothers during perinatal period (Paschetta et al. 2014).

Conclusion

Postpartum depression is a common psychiatric disorder causing impairment to normal postpartum period and bonding between mother and infant. It can be screened on regular visits and managed early through interdisciplinary collaborative model of care. Sensitizing the obstetricians and midwives on common mental health issues associated with pregnancy and postpartum may be beneficial in early detection of postpartum depression and timely intervention.

Definition

Precopulatory intrasexual competition occurs when individuals of the same sex compete directly for the opportunity to copulate with individuals of the opposite sex.

Introduction

Precopulatory intrasexual competition usually involves competition between males for the opportunity to copulate with receptive females. This phenomenon is thought to be responsible for the evolution of a variety of morphological traits, such as enlarged and elaborate male weaponry, and also behavioral traits, such as precopulatory mate guarding. When precopulatory intrasexual competition is particularly intense, it might also lead to the evolution of alternative reproductive tactics

among males, often resulting in male dimorphism (bimodality in the size of traits, such as horns, which creates two distinct male morphs). Precopulatory competition can also generate sexual conflict, where the evolutionary interests of the two sexes are not completely aligned. Finally, despite acting mostly on males, precopulatory intrasexual competition can also affect females under specific conditions.

Context, Causes and Consequences

Sexual selection results from the differential reproduction of individuals of the same sex due to their mating and fertilization success (Andersson 1994). This can result from: (1) individuals of one sex (typically females) choosing individuals of the other sex (typically males) with whom to mate and/or (2) direct competition between members of one sex (typically males) for reproductive access to receptive individuals of the other sex (typically females). The first mechanism is termed “intersexual selection” or “mate choice,” whereas the second mechanism is termed “intrasexual selection” or “male-male (more rarely female-female) competition” (Andersson 1994). Mate choice is the main driver of the evolution of sexual ornaments, whereas male-male/intrasexual competition is the main driver of the evolution of male weapons (Emlen 2008). Sexual selection is traditionally understood as acting in three different episodes, prior to mating (“precopulatory”), during mating (“pericopulatory”), and after mating (“postcopulatory”). Evidence for both processes of sexual selection, and across the three episodes, is ubiquitous in a wide range of animals, including humans.

Weapons and Fights

Throughout the animal kingdom, the reproductive success of females is primarily dependent on their fecundity, whereas that of males depends more heavily on their mating success. Greater variation in male reproductive success compared to female reproductive success is referred to as Bateman’s principle (Bateman 1948). Although still widely debated, the underlying cause for this discrepancy

is probably linked to the degree to which each sex invests in producing/rearing their shared offspring (“parental investment”; Trivers 1972). This phenomenon is thought to be as old as the evolution of sexual reproduction through anisogamy, i.e., the coexistence of a sex that produces large and generally immobile gametes (by definition females) and a sex that produces small and normally highly mobile gametes (by definition males). Because of anisogamy, females invest more in the offspring from the earliest reproductive stage. Indeed, their eggs, which are usually physiologically more costly to produce than sperm, begin to explain why females are limited by their fecundity and typically invest more in the offspring, while males, with their cheaper to produce sperm, are instead limited by their success in achieving matings. Recent mathematical models (Kokko and Jennions 2008), however, have criticized anisogamy and asymmetric parental investment as not sufficiently explaining traditional sex roles (females invest in the offspring more; males compete for females). Nevertheless, regardless of the causes for traditional sex roles, males are usually under stronger precopulatory intrasexual selection, the consequences of which are demonstrated by the evolution of male weaponry traits and combat (Andersson 1994).

Higher variation in the reproductive success of males, and their reliance on mating success, leads to males spending a great portion of their energy in producing and maintaining weapons that grow to seemingly exaggerated sizes, such as antlers, jaws, claws, highly elongated legs, and horns [on their heads or other parts of their bodies, including for instance thoracic horns in beetles (Emlen 2008)]. In certain groups both sexes bare weaponry that may serve a nonsexual function, for example, the naturally selected horns of male and female bovids (Bro-Jorgensen 2007), which are used as a defense against predators. However, for the majority of weapons in the animal kingdom, males are the only ones to produce them or produce them at a much greater degree of exaggeration than females. Interestingly, the nature of male-male fights can range from ritualized displays and sparring that involve mild physical

contact (Alvarez 1993) and no damage to brutal contests that cause severe damage to the contenders. Scenarios such as these are observed in Dawson's burrowing bees, for example, where fights between males often cause disabling injuries that lead to death (Alcock 1996).

Alternative Reproductive Tactics and Intrasexual Dimorphism

The production and maintenance of extravagant and exaggerated weapons can be extremely energetically costly to males, a cost that is often exacerbated by the long and sometimes brutal fights in which males engage. However, male combat theory predicts that weapons may function as assessment signals, and males will benefit if they are able to assess the potential of rival males and avoid fights with unbeatable opponents. In support, it is often observed that the most elaborate weapons rarely inflict real damage to opponents, but reveal and highlight subtle differences in male size, status, or physical condition [e.g., rhinoceros beetle horns (Eberhard 1979)], while unimpressive or inconspicuous weapons regularly inflict serious damage in male contests [e.g., spiders (Leimar et al. 1991)]. As a result of the high costs of producing or maintaining weapons and engaging in dangerous fights, small males of a variety of species have evolved tactics to completely avoid fighting (Oliveira et al. 2008). Instead, these males seek copulations through alternative means, such as sneaking undetected into a larger male's territory (Emlen 1997), searching for females that are not inside any territory (Alcock 1996), or pretending themselves to be females in order to get close to females without being chased away by larger males (Norman et al. 1999). Such alternative tactics are common within vertebrates, molluscs, arachnids, and especially insects.

Alternative reproductive tactics in males often consist of different mating behaviors that show high plasticity, so that the same individual can switch between tactics dynamically through the course of a breeding season, or even throughout the day, as in the butterfly *Lycaena hippothoe*, where the weather determines

whether a male defends a territory or actively patrols for females (Fischer and Fiedler 2001). In other cases, a male can only switch tactics a limited number of times, or only in one direction, as the damselfly *Calopteryx maculata*, where males switch from territoriality to a sneaking behavior as they age (Forsyth and Montgomerie 1987). Finally, alternative reproductive tactics can select for morphological specializations, leading to the evolution of dimorphic males, a phenomenon called male dimorphism or intrasexual dimorphism. In such cases, for example in many dung beetle species, the alternative tactics are irreversible, as fighter males develop enlarged horns that are absent in small sneaker males (Emlen 1997).

Precopulatory Mate Guarding

Intrasexual competition can also manifest through more subtle adaptations, such as mate guarding, where a male guards a female and directly prevents her from mating with rival males, a behavior that is particularly common in crustaceans when the period of female receptivity is short (Jormalainen 1998). In some butterfly species, males might even guard and fight for a chrysalis that contains an immature female going through metamorphosis, as a strategy to guarantee that they will be her first sexual partners (Mendoza-Cuenca and Macías-Ordóñez 2010). Interestingly, male birds that offer paternal care may guard their partner but only attempt to mate with them after being paired for several days, presumably to guarantee that the clutch is not sired by another male (Owens et al. 1995).

Mate guarding is also quite commonly observed after the mating has already occurred, but in these cases the behavior is regarded as a strategy to avoid postcopulatory competition processes, such as sperm competition. In fact, whether males guard the females prior or after copulation can be indicative of sperm precedence in the species: if the first male to mate fertilizes most of the eggs (first male sperm precedence), males tend to guard their mates prior to copulation; whereas if the last male to mate is the one who fertilizes most of the eggs (last male sperm

precedence), males tend to guard their mates after copulation. Evidence for this relationship, and its connection with the internal morphology of the female reproductive tract, which in itself predicts the pattern of sperm precedence mentioned above, came originally from studies of spiders (Eberhard et al. 1993).

As an example of “remote” mate guarding, and as an attempt to prevent or delay inseminations by rivals, the males of many taxa (e.g., insects, spiders, reptiles, mammals) deposit mating plugs to obstruct the female reproductive tract. When 100 % effective, mating plugs will prevent sperm competition and thus be beneficial to males by simultaneously providing paternity assurance while also allowing them to seek out and copulate with additional females (Sutter et al. 2015). As detailed in the following section, male prevention of postcopulatory sexual selection may not be beneficial to females.

Precopulatory Intrasexual Competition and Sexual Conflict

Sexual reproduction has historically been viewed as an act of cooperation. However, the complete alignment of male and female interests over reproduction is one extreme along a continuum for which the other extreme is complete conflict between the sexes (Arnqvist and Rowe 2005). Sexual conflict, which occurs when the evolutionary interests of the two sexes are not in accord, enforces opposing selection pressures on males and females. As mentioned previously, males and females often differ in their investment in reproduction, leading to distinct roles with different fitness optima for each sex. As both optima cannot be reached simultaneously, selection favors each sex to maximize its fitness at the expense of the fitness of the other sex. Cycles of adaptations and counteradaptations between the sexes can generate a perpetual tug-of-war, resulting in male–female coevolution and the rapid evolution of sexual traits (Arnqvist and Rowe 2005). Sexual conflict is ubiquitous in nature and can be observed at multiple levels, extending from courtship and mating to fertilization and parental investment.

Mechanisms and strategies of precopulatory intrasexual competition may not always align with the females’ best interest and thus generate sexual conflict (Bonduriansky and Rowe 2003). For example, dominant males that win intrasexual contests may increase their own mating opportunities by excluding rivals, but females in turn have reduced fitness when mating with dominant males (Wong 2004). Females may then discriminate against dominant males in favor of subordinates to increase their own fitness. Further, successful mate guarding attempts will prevent females from copulating with more than one male and therefore potentially hamper female fitness. Multiple-mating by females (polyandry) has been shown to be a profitable mating strategy when females gain either direct benefits from males (e.g., the nuptial gifts of insect species, Gwynne 2007) or via more indirect, subtle means that lead to the improved genetic quality of their offspring (i.e., the good and compatible genes models for the evolution of polyandry, reviewed by Jennions and Petrie 2000). In bird species in which females benefit from multiple-mating, and thus seek copulations with males other than their social partner (extra-pair copulations or EPCs), selection will favor traits that simultaneously enhance the male’s ability to guard his mate and the female’s ability to evade mate guarding. Female superb fairy-wrens have quite successfully adopted a tactic of acquiring EPCs by seeking out extra-pair males prior to dawn, presumably to avoid detection by their social partner (Double and Cockburn 2000).

Female-Female Competition

The ubiquity of the traditional mating roles, in which males fight over access to females or resources and females choose males, has led to studies of intrasexual competition focusing mainly on male-male competition. By contrast, precopulatory competition among females, which is not that rare and seems to act more commonly through male mate choice than female-female competition, has received considerably less attention.

A reversal of the typical mating roles might occur under specific conditions. For example, a

bias in the operational sex ratio (OSR) has been shown to predict which sex will compete for access to mates and how intense the competition might be (Kvarnemo and Anhesjö 1996). That is, mating competition is expected to become more intense as the OSR deviates further from equality, and the sex that is in “excess” (the sex predicted to become the predominant competitor for access to mating partners) will experience stronger sexual selection (Kvarnemo and Anhesjö 1996). When males are the limiting sex, females might compete directly for access to males, for resources that they acquire from them, including food and territories (e.g., nest sites), or for the protection they offer (Stockley and Bro-Jørgensen 2011 and references therein). When males vary in the quantity or quality of the resource/s they provide, females are expected to compete for mates as an indirect manifestation of resource competition. Consistent with this idea, women often compete for marriage partners in human societies that are characterized by monogamy and strong wealth differentials among males (Stockley and Bro-Jørgensen 2011). In food-stressed katydid populations, the low proportion of males able to produce a nuptial meal (the spermatophylax that envelops the spermatophore) leads hungry females to foraging for “mating meals” and consequently results in females competing for access to males (Gwynne and Simmons 1990). In the Chacma baboon, where sexually selected infanticide by unrelated males is a potential threat to offspring survival, females rely on support from male “friends” (with which they are more likely to mate) to help protect their offspring (Stockley and Bro-Jørgensen 2011).

In some cases it may not be the males or the resources that they provide that are limited, but instead sperm. Traditionally, limitations to male sperm supplies were not thought to influence the evolution of mating strategies. However, it is now known that this is not always the case, and sperm depletion among males may be promoted by several factors, such as a synchronization of female receptivity or breeding periods, high rates of polyandry, or unanimous female mate preferences that tips the OSR towards a female bias. The elicitation

of male sperm limitation and female-female competition for mates due to factors such as these are seen among ungulate species that experience strong breeding synchrony and high rates of female multiple-mating (Stockley and Bro-Jørgensen 2011). Whether females are competing for access to males, their resources or their sperm, precopulatory intrasexual female competition, in theory, could lead to the evolution of exaggerated traits used to outcompete rival females in contests, analogous to male sexually selected traits. However, in addition to survival costs, the development of female weapons seems to be limited by fecundity costs (Clutton-Brock 2009). Certainly, an absence of these traits in nature suggests that precopulatory intrasexual selection is not the same potent evolutionary force for females than it is for males.

Conclusion

Precopulatory intrasexual competition is a ubiquitous phenomenon that results from the competition between males for reproductive access to receptive females and more rarely between females for access to males or their resources. For males, this type of competition can be fierce and is recognized to have selected for a multitude of morphological (weapons) and behavioral (precopulatory mating guarding) traits. Often small males are unable to compete, and in such cases precopulatory intrasexual competition might select for alternative reproductive tactics that can even lead to the evolution of bimodality in the sizes of males and/or their weapons. If females benefit from mating with males that are not the winners of male-male fights, intrasexual competition can also lead to sexual conflict.

Definition

The predator confusion hypothesis (Sherman 1977, 1981) predicts that group-living animals are adapted to make alarm calls that distract or confuse predators, thus lowering the predator's chances of consuming any prey individual. In birds and mammals, some species make anti-predator vocalizations that are thought to confound predators (Ficken 1989). When a single individual vocalizes in response to a predator, other group members will echo that call, creating disorder and preventing the predator from being successful.

Introduction

Animal species ranging from invertebrates to birds to mammals are targeted by predators for food. These prey species have evolved various behaviors to help them avoid predation, including crypsis, where animals hide or conceal themselves to escape predator attention; swarming, where animals move together while concentrated in a small space; mobbing, where animals approach a predator for the purposes of intimidating it; and/or alarm calling, where animals make loud vocalizations in response to the detection of threats (Charnov and Krebs 1975; Jeschke and Tollrian

2007). Alarm calls draw attention to the individuals who vocalize and can result in a higher chance of predation in some species, such as several Sciuridae rodents (Maynard Smith 1965; Sherman 1977). In other species, such as birds and primates, alarm calling may be one of several means by which prey animals reduce their chances of predation by confusing predators (Cresswell 1994b; Wheeler 2008). Alarm calls are adaptive if they drive predators away and/or enhance the survival rates of a caller's relatives (Maynard Smith 1965).

Several non-mutually exclusive hypotheses have been proposed in explanation for the adaptiveness of alarm-calling behavior, including the predator confusion hypothesis (Wheeler 2008). This hypothesis predicts that for group-living species, an alarm call by one individual that is echoed by other group members may distract the predator and also reduce the chance of single individuals being targeted through the dilution effect (Bertram 1978). Group members may approach and noisily vocalize toward a predator, which has the effect of confusing the predator and reducing its chances of prey consumption (Sherman 1977). The predator confusion hypothesis is one of several explanations for the evolution of antipredator vocalizations in group-living animals.

Alarm Call Creates Confusion

The predator confusion hypothesis is based on the idea that prey animal behaviors misdirect or confound predators, thus decreasing the likelihood of successful predation events (Charnov and Krebs 1975). This provides a survival advantage to the prey, stemming from predator confusion occurring in one of several forms. Prey may confuse predators through camouflage, swarming or aggregation, mobbing, and/or alarm calling.

While spiders are known to confuse predatory wasps through the camouflage provided by web decoration (Tseng and Tso 2009), and prey including invertebrates, fish, and birds are known to decrease their chances of predation by moving in swarms (Jeschke and Tollrian 2007), some mammals and birds confound predators through alarm

calling. When a predatory threat is seen, prey animals make alarm calls in response. Vocalizing reveals the caller's location to predators, and, for animals including various Sciuridae rodents, this causes the caller to be targeted by the predator (Sherman 1977, 1981). Because alarm calling does not increase the chance of survival for these prey species, other explanations are useful in understanding how alarm calling has persisted over evolutionary time (Maynard Smith 1965). For group-living prey animals, the predator confusion hypothesis predicts that when an individual makes an alarm call, other group members will also make alarm calls, in an attempt to confuse the predator and drive it away (Wheeler 2008). Group-wide alarm calling may divert a predator's attention, preventing it from being able to focus on a single prey animal for pursuit and generally causing disorder and confusion (Sherman 1985). The predator is thus less successful at killing and consuming prey as a result of the chaos caused by antipredator vocalizations (Sherman 1977).

Alarm calling has been theorized to create confusion for the predators of a number of animal species (Charnov and Krebs 1975). Whenever an alarm call is produced in a group-living species, this can create disorder as all group members echo this alarm vocalization and rush to escape from this threat. The unpredictable, erratic vocalization and movement behavior by the prey is thought to distract the predator, giving each animal in the group an increased chance of escaping (Jeschke and Tollrian 2007). Alarm calling has been proposed to cause confusion for the predators of rodents, birds, and primates (Sherman 1977, 1981; Ficken 1989; Bolt et al. 2015). For rodents including the Belding's ground squirrel (*Urocitellus beldingi*), individuals vocalized and moved to conceal themselves in response to predatory threats (Sherman 1977). These movements and calls were hypothesized to confuse predators and prevent predation, although empirical evidence does not support this and alternate hypotheses for the adaptive function of alarm calling in ground squirrels have received greater support (Sherman 1977, 1981). The predator confusion hypothesis has also been applied to other vocalizing animal species. Birds including black-capped

chickadees (*Poecile atricapillus*), Steller's jays (*Cyanocitta stelleri*), and Clark's nutcrackers (*Nucifraga columbiana*) engage in mobbing behavior by gathering around potentially dangerous predators while making group-wide alarm vocalizations at their own rates (Ficken 1989). These group-wide antipredator vocalizations were suggested as adaptations that add to predator confusion and reduce the chances of single animals being consumed (Ficken 1989). For primates such as the ring-tailed lemur (*Lemur catta*), antipredator vocalizations initiated by one group member are also made by other group members, which was suggested to cause confusion for predators (Bolt et al. 2015). However, although these prey species have alarm calls with the potential to cause predator confusion, it is unknown whether the calls of jays, chickadees, nutcrackers, and lemurs do confound predators. The alarm calls of these animal species have not been empirically tested for predator effects, and more direct observations of predator-prey interactions are needed to further evaluate this hypothesis.

Confusion Enables Escape

Group-wide alarm calling in a variety of prey species has been suggested to confuse predators, by distracting predators from targeting specific individuals and better allowing prey to flee and avoid consumption (Jeschke and Tollrian 2007). Although the predator confusion effect has been proposed for the alarm calls of various prey animals, few species have been tested for direct evidence that alarm calling causes predator confusion and better enables prey to escape. This stems from the difficulty of observing predation events in the wild and the difficulty in separating various non-mutually exclusive explanations for behavior (Bradbury and Vehrencamp 1998). A handful of alarm-calling rodents, primates, and birds have been tested experimentally or observationally for evidence of the predator confusion effect, with mixed results. For the redshank bird (*Tringa tetanus*), there was no higher chance of mortality for birds who alarm called while in flight, likely due to confusion for the predatory sparrow hawk

(Cresswell 1993). For the Belding's ground squirrel (*Urocitellus beldingi*), alarm calls showed no evidence of confusing predators since weasels and coyotes followed and killed the alarm callers at higher rates than non-callers (Sherman 1977, 1981). Tufted capuchin (*Cebus apella*) alarm-calling behavior was also tested for confounding effects and thought to be unlikely to confuse predators (Wheeler 2008).

The pursuit deterrence hypothesis (Sherman 1977) is a related and overlapping hypothesis which suggests that alarm calling is adaptive for prey because it discourages predatory targeting and leads to increased survival for the caller. Animal species ranging from birds to ungulates and primates have been found to have alarm calls that deter predators, although it is unknown whether predator confusion is a causative factor in this deterrence. Birds such as the Eurasian skylark (*Alauda arvensis*), ungulates such as the klipspringer antelope (*Oreotragus oreotragus*), and primates including the Diana monkey (*Cercopithecus diana*) are known to use alarm vocalizations to drive away stealth predators (Tilson and Norton 1981; Cresswell 1994b; Zuberbühler et al. 1997). In each of these cases, vocalizations are thought to deter predators through intimidation and/or the loss of the element of surprise, but there may also be some element of predator confusion involved, since the predator deterrence and predator confusion hypotheses are not mutually exclusive (Wheeler 2008). Further study is needed to elucidate whether alarm calls may deter predators through confusion in these species.

Although little direct evidence exists for predator confusion caused by alarm calling, the general phenomenon of predator confusion as a result of prey behavior is widespread and has support from a variety of taxa. Further evidence of confusion exists from prey species that confound predators through camouflage or swarming.

Camouflage is known to be used by spiders to confuse wasp predators, since those spiders who decorate their webs have a lower chance of being consumed (Tseng and Tso 2009). Web decoration is thought to divert predator attention by acting as a decoy, thus concealing the spider's actual

position on the web (Blackledge and Wenzel 2001). Swarming happens in various group-living animal species and has been found to confuse predators for many of these (Jeschke and Tollrian 2007). Swarming is when many conspecifics are in motion while in very close proximity, and it is the presence of many individuals moving together in an unpredictable way that is thought to make it difficult for predators to successfully attack (Olson et al. 2013). Predators are unable to focus on individual prey animals because they divide their attention between many visible members of a swarm, which results in a decreased chance of capturing a single individual (Dukas 2002).

Evidence of predator confusion through prey swarming behavior is widespread and exists for prey taxa including fish, birds, and invertebrates such as nematodes and common water fleas (*Daphnia* spp.) (Neill and Cullen 1974; Cresswell 1994a; Jensen and Larsson 2002; Jeschke and Tollrian 2007). The majority of predator-prey groups tested showed evidence of predator confusion (Jeschke and Tollrian 2007; Olson et al. 2013), revealing this as a widespread anti-predator adaptation for social prey organisms. Predators who detect prey based on both tactile and visual systems are affected, while prey species that move faster, move more erratically, and/or aggregate in larger groups are more likely to elude capture (Jeschke and Tollrian 2007). The predator confusion hypothesis is well supported by evidence from animal behavior in general, although alarm calling in particular has yielded little direct evidence of causing predator confusion to date.

Conclusions

A greater number of vocalizing and group-living prey species need to be studied for evidence of predator confusion. Although the predator confusion hypothesis is well supported with respect to swarming behavior in various animal taxa, evidence of alarm vocalizations causing predators to be less successful due to confusion is lacking (Ficken 1989; Olson et al. 2013). However, the predator confusion hypothesis stands alongside

the predator deterrence hypothesis as one of several cogent, non-mutually exclusive hypotheses for the evolution of alarm-calling behavior. In the absence of direct evidence for predator confusion, it remains a compelling and plausible theoretical explanation for the evolution of risky vocalization behaviors by group-living animal species.

In prey animals, it is widely accepted that living in groups reduces the risk of predation and that this occurs via a number of mechanisms, such as collective detection of predators (see “[Grouping and Predation](#)”). While this explains aggregation over space, *animals vulnerable to predators are often aggregated in time, where there is temporal synchrony in the period that individuals are exposed to predators*. This synchrony in timing “swamps” the response of predators, so that the overall rate of predation does not increase proportionally with the greater availability of prey. The result is a reduced risk of predation per individual prey, and predator swamping provides an evolutionary explanation for the collective emergence of mayfly larvae (Sweeney and Vannote 1982), cicadas (Williams et al. 1993), some species of sea turtle hatchlings (Santos et al. 2016), the young of some ungulates (Milner-Gulland 2001) and birds (Nisbet 1975) through synchronous breeding, and even mast seeding in plants, where large numbers of seeds are produced in some years within a population of plants and very few in

others (Kelly 1994). These examples demonstrate both the diversity of living organisms that show synchronous emergence, and also that this synchrony can occur within a set (clutch, brood) of related offspring (e.g., sea turtle hatchlings) and between individuals within a population (as occurs in mast seedings (Kelly 1994) and breeding aggregations (Milner-Gulland 2001; Nisbet 1975)). While predator swamping is often used to explain synchrony in reproductive contexts, it has also been used to explain behavioral synchrony, where individuals expose themselves to risk in a collective and coordinated manner. For example, the aquatic African clawed frog (*Xenopus laevis*) can breathe air at the water surface and increases the synchrony of this behavior after a disturbance, suggesting that this synchrony is a response to potential risk (Baird 1983).

A number of studies have shown that the risk of predation per prey individual decreases when the number of prey available increases (Nisbet 1975; Santos et al. 2016; Sweeney and Vannote 1982). A major explanation for this effect is handling times. All foragers are subject to a handling time, which is determined by the time required to capture, subdue, consume, and/or digest a food item. This places an upper limit on the rate that prey can be killed and consumed, and if the time that prey are available is limited (for example, as newborn individuals grow to be less vulnerable), the total number of prey consumed will be limited as well. The result is a “type II functional response,” where the consumption rate of predators increases with prey density but saturates at high densities (Holling 1959). If prey emergences are patchily distributed over space, the time required for predators to locate and move to the prey can have a similar effect, so that the spatial aggregation of predators to the prey patch is delayed relative to the time period that prey are available for capture. In a recent study, Santos et al. (2016) argued that both of these effects are likely to explain why individuals often hatch synchronously within nests of sea turtles. In their study system of green turtle (*Chelonia mydas*) hatchlings being preyed upon by the yellow crab (*Johnnarthia lagostoma*) as the hatchlings crawl to the sea, the large size of the hatchlings relative to the predators results in long handling times

where the prey are consumed and digested. Although crab densities were relatively high at the study site, the limited sensory range and mobility of the crabs searching for prey in the dark also makes it unlikely that the crabs could respond to a hatching event quickly enough for there to be a large increase in local predator density around a hatching nest. Once the crabs in the local vicinity have finished consuming their first captured prey, and those a further distance away could respond to the emergence, the hatchlings would have already reached the relative safety of the sea.

Although predator swamping is used to explain reproductive (Ims 1990) and behavioral (Baird 1983) synchrony, predator swamping through temporal synchrony can also occur via prey moving together in groups (see “[Grouping and Predation](#)”). If prey groups are mobile relative to their predators and do not show predictable patterns of movement, it is unlikely that predators will be able to track their location, so when prey are encountered, the time available to attack and consume prey is limited. With a handling time that limits the rate of capturing prey, this results in a predator swamping effect. In contrast, evenly or randomly distributed prey will be encountered more frequently, and the time between encounters will allow predators to handle prey and be more likely to be ready to consume prey in the next encounter. This is essentially attack abatement (Turner and Pitcher 1986), where the rate of attacks on a group is less than proportional to group size, and only a limited number of prey can be killed upon each encounter (also see “[Grouping and Predation](#)”). In general, the term predator swamping is applied to cases where prey can be either in a safe or vulnerable state, and the transition to the vulnerable state is synchronized with other individuals in time. Attack abatement is instead applied to prey aggregated in space, where being vulnerable depends on whether a group is detected by a predator. There is nonetheless a close link between mass emergences of prey and when prey are actively social and form groups.

While predator swamping is a simple and hence parsimonious explanation for synchronous emergence, alternatives have been suggested for

some systems. A high density of prey, even if they are not actively forming groups, can still result in antipredatory benefits similar to those documented for animals living in groups (see “[Grouping and Predation](#)”), such as the confusion effect (Baird 1983). Synchrony in emergence may be a direct response to variation in available resources rather than as a strategy to swamp predators. However, it is unlikely that environmental conditions will vary over time in such a punctuated manner that it can explain synchronous emergence in most systems, i.e., environmental variation will rarely perfectly match the variation in prey abundance over the appropriate temporal and spatial scales. Mast flowering in some plants can be explained by environmental prediction, where a cue triggers plants to respond by increasing reproductive effort to take advantage of favorable conditions that are expected to follow. This is likely to explain greater reproductive effort in some plants after fire, which releases nutrients into the soil and reduces competition for their offspring (Kelly 1994). The mast flowering of other plants can also be explained by wind pollination being more efficient where the probability of fertilization increases with the number of flowers, and this is well supported by empirical studies (Kelly 1994).

Synchronous emergence is not always beneficial for reducing predation risk, as predators can minimize handling times by storing killed prey, or aggregate around emergences if they are highly mobile. Where predators can switch between prey types or are mobile enough, synchronous emergence at a local scale can actually increase the risk of predation for synchronous rather than asynchronous prey (Ims 1990). For predator swamping to be effective, synchronous emergences of prey need to be difficult to predict by predators; if they are not, predators will move toward and aggregate around the emergence or even time their own reproductive effort so that the predator population size increases with the greater abundance of prey. As with understanding the antipredatory benefits of living in groups, the behavior of predators in response to mass emergences of prey needs to be studied, as well as the behavior of the prey, to fully understand predator swamping.

An animal that preys on other animals for food.

Introduction

Bipedal locomotion introduced a number of profound changes for hominins. While ancestors of humans primarily lived in trees, it is believed that ancestors of hominins were the first to move out of trees and adjust to living in new terrains, such as savannahs. As a result, evolution took its due process and therefore induced changes in our ancestors to adapt to their new environment and accommodate to the new prey and means of killing them. As a result, hominins developed the ability to walk on two legs, also called *bipedal locomotion*. Bipedal locomotion changed a number of behaviors in hominins, but among them are their predatory instincts and especially the way they hunted (Lovejoy et al. 2009).

Effects on Hunting Behaviors

Given that bipedal locomotion frees up usage of the upper body and hands rather than using them to walk, this completely shaped the behavior of how these early hominins would hunt their prey. While prior to bipedal locomotion much of the hunting was executed in trees, these hominins now had entire savannahs to traverse using their two legs and therefore acquired the ability to run long distances. Running long distances was pivotal to hominin survival and therefore was a huge advantage in early human life. A key component to this was endurance rather than short sprints which were indicative of many preys that these hominin would hunt. While certain animals such as gazelles could quite easily outrun an early hominin, the hominin soon developed the ability with bipedal locomotion to be able to jog these distances for extended periods of time. The prey would eventually tire out from its short bursts of sprints and be forced to rest, to which the

hominin would then be able to execute its prey after its long distance chase. Behaviors like these were exclusively capable because of bipedal locomotion, as the change in body shape and posture allowed for longer, endurance-based runs rather than quick bursts of speed, as detected by footprints found of early hominids (Raichlen et al. 2010).

In addition to endurance-based running, bipedal locomotion had a profound effect on predatory behavior in hominins in many other ways, including vision. While living in trees, posture was developed to be able to climb trees and also typically had an arch in the spine as seen in many current primates in the wild. As a result, looking forward was quite difficult and led to a change in vision and the ability to perceive their surroundings. However, bipedal locomotion had the effect of forcing the spine into a straight, vertical orientation, not only changing the physiological structure of the hominin but also the way they looked out at their surroundings. Due to the lack of curvature in the spine, hominins now had access to a much wider horizon and field of view as compared to their previous orientation. As a result, this was extremely advantageous in a savannah-like environment, given the lack of structures such as trees blocking field of view. While living in forests required being able to climb to assess their surroundings, the move to savannahs meant wide stretches of flat land, to which being able to horizontally look around and assess one's environment was pivotal to survival, as well as to predatory behavior (Raichlen et al. 2008).

Lastly, bipedal locomotion also allocated two free limbs as compared to those limbs being used for locomotion. As a result, hominins developed the use of their arms, which allowed for countless behaviors that we can even see we use today. Behaviors such as picking up objects, grabbing, and even throwing became pivotal tools in our ability to hunt and survive on the savannah. As hominins continued to develop, they utilized the use of tools and weapons in their hunts, which they would not have been capable of doing had they not developed to bipedal locomotion. The

free use of their hands and arms then allowed them to create weapons in the first place, as well as develop throwing motions to be able to take down animals from a distance. Doing so allowed for hunting animals that prior to this development would have been faster than them or would have required a great deal of endurance and effort, thereby maximizing their resources while limiting expenditure of their energy.

Conclusion

These changes and adaptations made bipedal locomotion essential to the way we survived by hunting animals in our newfound savannah-like environment. Everything from increased endurance due to a change in physiological body shape, changes in vision due to the placement of the skull on top of the body, to the free usage of hands to create weapons and use them in throwing motions allowed these hominins to adjust to their change in environment and continue to survive and reproduce, eventually becoming the homo sapiens we see today.

Definition

The fast, seemingly automatic detection of threatening words and images, coupled with delayed disengagement from their location and more durable memories of threat-relevant information.

Introduction

At the intersection between emotion and the evolutionary and cognitive psychology literatures lies a powerful adaptation: the seemingly automatic attentional capture of threatening stimuli in one's environment. For example, angry faces are quickly spotted among happy ones, and snakes and spiders are easily detected among neutral backgrounds of flowers, mushrooms, and non-threatening animals. The current review discusses common findings with these visual search and attentional cuing tasks, with a special emphasis on the mechanisms underlying attentional capture. Recent findings from the related adaptive memory literature also suggest that effects associated with threatening stimuli – faster detection, slower disengagement, and so on – can also

translate into more durable memories. Together, these findings support evolutionarily-derived hypotheses for cognitive processes and abilities.

Threats, Fears, and Attention

In the classic visual search paradigm, participants are presented with arrays of static images and asked to indicate whether the images belong to the same or different categories. As the images contain a variety of fear-relevant (e.g., snakes, spiders) and fear-irrelevant (e.g., flowers, mushrooms) stimuli, these investigations extend the typical visual search paradigm (i.e., assessing differences in search times as a function of varying array size) to consider whether search time also varies in accordance with the evolutionary significance of threat-detection. Öhman, Flykt, and colleagues (Flykt 2006; Öhman et al. 2001; Soares et al. 2009) have demonstrated a robust advantage for snake and spider detection, when presented among neutral backgrounds of flowers and mushrooms. These advantages in search times do not appear to be affected by grid size, nor do they rely on specific combinations or locations of images within the array. Furthermore, while some of their work has shown some additional sensitivity to images of snakes (Öhman et al. 2001), experiments sampling spider phobic individuals have shown comparable sensitivity to spider detection among neutral backgrounds (Soares et al. 2009).

Flykt (2006) has argued that search times involve a sequence of controlled searching for the target stimulus, automatic processing of the target, and action preparation in accordance with the target's associated level of threat. The more salient targets – those posing a potential threat – carry a great deal of emotional relevance and facilitate the search process, requiring shorter search times. Other, related work has shown that a *moving* threat (i.e., the more dynamic nature of a moving cockroach, relative to a moving ladybug) is particularly distracting in other attention-based tasks (Carretié et al. 2009). These findings have been replicated with face stimuli, with more efficient searches for moving threatening faces among moving friendly faces,

than vice versa (Hortsmann and Ansorge 2009). Thus, motion provides valuable information: a greater signal of imminent danger in one's environment. Simple procedural modifications have also shown that the advantages associated with threat detection in visual search can be observed among infants and young children, including those as young as 5 months old (LoBue 2010; Rakison and Derringer 2007). These findings indicate that attentional biases to spiders and related fears may originate from a stored template: one that may not rely on any prior experience with the threatening stimulus.

Researchers have also adapted attentional cuing paradigms for these threat-related investigations. Fox et al. (2001) have asked whether threatening stimuli automatically attract attention or whether they prevent disengagement of attention to other – positive or neutral – stimuli. They found that the presence of threatening words (e.g., fail) and angry faces delayed the disengagement component of visual attention, slowing participants' responses when these stimuli cued invalid locations (i.e., those other than the target location), relative to positive and neutral cued locations. Related findings with eye-tracker methodology have shown that participants are generally more distracted by dangerous stimuli (e.g., lions, snakes) than they are distracted by non-dangerous stimuli (e.g., impala, lizards), and these distractions are a function of both faster detection times (i.e., the time spent locating the lion) and increased fixation duration (i.e., the time spent looking at the lion) (Yorzinski et al. 2014). Thus, the delayed disengagement hypothesis is supported by both behavioral and eye movement data.

Additionally, Fox et al. (2001) have found that disengagement is particularly delayed among high-anxious participants, who in their fifth experiment took significantly longer to disengage from locations with threat-related words relative to low-anxious participants. Threatening faces provided similar results, with increased attentional dwell time to both real and schematic faces among high-anxious participants. Thus, an anxious individual's greater propensity to avoid dangerous situations is particularly apparent in these

experimental manipulations: an avoidance with adaptive value. Together, these adaptations help humans respond appropriately in times of threat, with findings from both the visual search and cuing paradigms supporting the notion that threatening stimuli in the foreground and background grab and maintain our attention.

Fox et al. (2007) have hypothesized a flexible, evolved fear module to account for this body of literature. In their visual search experiments, they compared search times for phylogenetic (i.e., ancestral fears of snakes and spiders) and ontogenetic (i.e., modern fears of guns and syringes) fears, with fear-relevant images presented among a variety of neutral backgrounds: flowers and mushrooms, as well as toasters and electric kettles. This particular comparison examines whether threat-detection varies as a function of the particular age of the threat: Were threats present at the time of mammalian evolution granted some priority or threat superiority? Their findings indicated a general threat-superiority effect, with images of snakes and guns attracting attention more effectively than neutral images, and no advantage of ancestral threat-detection. Supporting related work, their data indicate that stimuli appraised as highly relevant – threatening targets, moving objects, and so on – garner more attention in the present moment.

Related Findings and Conclusions

Recent findings have also shown that the attention-grabbing power of threatening stimuli can promote more lasting memories than neutral stimuli. The adaptive memory literature hypothesizes that the human memory system evolved to solve and remember fitness-relevant problems: those problems that engaged survival-relevant thought processing. In their seminal work, Nairne et al. (2007) found that participants' memory for neutral, concrete items (e.g., screwdriver, pan) was enhanced when considering how they might aid in locating survival materials and providing protection from nearby predators. This mnemonic improves upon other, well-known strategies, including those that engage deep, meaningful word processing (see Kazanas and

Altarriba 2015 for a recent review). Thus, the mere thought of predators – without needing to visualize them – may facilitate more efficient cognitive processing. In an interesting twist, researchers have also found that considering particularly salient predators – including demons and zombies embodying superior, supernatural capabilities – provides some additional memory benefit (Kazanas and Altarriba 2017; Soderstrom and McCabe 2011). Data collected at the intersection between emotion, evolution, and cognition, using a variety of tasks, have drawn similar conclusions: Engaging the predator-avoidance mechanism in times of threat is a combination of fast detection, slower disengagement, and durable memory formation.

Definition

Memory systems use the experience to expect what will happen in the present and future and decide how to behave in this circumstance.

Introduction

In 1989, researchers John R. Anderson and Robert Milson have stated that the basic principles of memory systems are to optimize the information retrieval to solve the current problems that memory systems encounter. Memory systems use their optimization algorithm to predict what kind of memory will be required to solve the current situation (Anderson and Milson 1989) and retrieve relevant and timely information to facilitate decision-making (Klein et al. 2002). This manageable number of previously stored information which people recall will be further utilized to predict what will happen in the future and frame the future behavior.

Predicting Events

Generally, the owner of memory systems is able to predict the event which will happen at a certain possibility based on the memory of a specific event or the summary knowledge which is abstracted from the repeated experience of similar episodes (Schank 1982). According to Schank (1982), this knowledge structure enables people to know what to expect and how to behave when facing an event of a similar situation. Researchers sometimes describe it as schema-driven memory (Graesser 2013) or script-based learning (Schank 1982). These predictions are not accurate all the time. They sometimes turn out to be wrong due to the complicated internal and external conditions. In these cases, people will remember these events with or without awareness in order to make a better prediction in the future (Klein et al. 2002).

Predicting Behaviors

Memory systems use the information required in the past to facilitate present and future behaviors

(Klein et al. 2002). With the experience, people can make an appropriate decision which people believe is the best solution to the current problems. The memory-based decision involves the retrieval of useful information which was stored in the past from memory and the construction of judgment based on this information. For example, the prediction of the forthcoming events plays an important role in how people behave now and next.

Memory produces transient or permanent long-term behavioral modifications by acquiring information about the past and current situation (Lorenzini et al. 1999). In some cases, these behavioral changes are performed without awareness. This kind of facilitation or change can contribute to habit learning, priming, or skill acquisition reliant on an unconscious recollection of prior learning episodes (Schacter et al. 1993).

Conclusion

Memory systems have undergone a long period of evolution to be capable to guide people behave appropriately in the present and future based on the information required in the past (Klein et al. 2002). However, little evidence has shown whether predicting events and behaviors are the designed function of memory systems or the functional product of evolved adaptations.

Definition

Grandparental investment can be basically defined as any contribution directed toward grandchildren by grandparents. Grandparental investment can include emotional support, physical care, and financial aid, and may also be indirect (e.g., through supporting the grandchildren's parents). Typically, there are costs associated with grandparental investment (e.g., time or money), which are dependent on the nature of the investment. From an evolutionary perspective, grandparents are predicted to gain indirect fitness (i.e., ensuring the

proliferation of their genes) from grandparental investment, either through increasing the number of grandchildren by investing in their adult children to increase fertility or by increasing the well-being and survival of their grandchildren.

Introduction

Grandparental investment is determined by the length of time grandparents are simultaneously alive with their grandchildren, in the way that when shared lifetime between grandparents and grandchildren increases, so do the grandparents' possibilities to invest. During recent centuries, the shared lifetime between grandparents and grandchildren has increased substantially (Chapman et al. 2017), and in present-day societies, grandparents and grandchildren have more shared lifetime than ever before (Coall and Hertwig 2010).

Although the length of time grandparents and grandchildren share has increased, it does not alone drive the patterns of grandparental investment. Fertility and mortality declines mean that more grandparents are available to grandchildren, while there are fewer grandchildren to invest in, so there is less competition between siblings and cousins for grandparental investment. Grandparents today are also healthier and wealthier than before. Finally, technological advances and rapid long-distant travel mean that even distant grandparents can easily maintain contact with their grandchildren. Thus, grandparents today have great opportunities to invest time and other resources in their descendants.

Genetic Relatedness

Although grandparents are known to invest a large amount of time and resources in their grandchildren, all grandparents tend not to invest equally (Tanskanen and Danielsbacka 2018). The inclusive fitness theory (Hamilton 1964) predicts that biological grandparents should invest more in grandchildren compared to non-biological grandparents. The relatively scarce amount of studies

detecting differences between biological and non-biological grandparents has indicated that, in accordance with the theory, investments are more often made by biological than by non-biological grandparents. For instance, using data from 11 European countries, it was found that biological grandparents more likely provided childcare at least weekly to their grandchildren compared to non-biological grandparents (Coall et al. 2014). Moreover, two recent studies using data from the USA and Germany showed that biological grandparents invested more in grandchildren than step-grandparents (Gray and Brogdon 2017; Pashos et al. 2016). Finally, a US study detected the role of genetic relatedness in two-mother families and asked whether grandparents from the biological mothers' side invest more than grandparents from the non-biological mothers' side. More regular contact between children and grandparents from the biological mothers' side than from the non-biological mothers' side was detected (Patterson et al. 1998).

Sex and Lineage

In addition to genetic relatedness, grandparental investment in their grandchildren tends to vary by sex and lineage. One of the most common findings in grandparental investment studies conducted in contemporary Western societies is that maternal grandmothers invest the most, followed by maternal grandfathers, paternal grandmothers, and finally paternal grandfathers (Euler 2011). This biased grandparental investment pattern has been found in several societies and for many different grandparental investment variables, for instance, childcare, emotional support, and monetary transfers.

Perhaps the most important evolutionary theory explaining this biased investment pattern by grandparent types is based on paternity uncertainty (Daly and Perry 2017). Only maternal grandmothers can be 100% sure that they are related to their grandchildren, while maternal grandfathers (via themselves and their daughters) and paternal grandmothers (via their sons and sons' children) have one uncertain link of

paternity. Paternal grandfathers are in the most uncertain position and have two uncertain links of paternity (via themselves and their sons and via their sons and sons' children).

Nonetheless, the cultural context may remarkably shape the biased grandparental investment pattern. In patrilocal societies, where women become part of their husbands' family after marrying, it is observed that paternal grandparents invest more than maternal ones (Daly and Perry 2017; Pashos 2017). In patrilocal societies, grandchildren usually live nearer to the men's than the women's relatives, meaning that the grandchildren are likely to interact with their paternal grandparents constantly and may see their maternal grandparents only occasionally. This situation also means that paternal grandparents can become closer to the grandchildren than maternal grandparents. The opposite tends to be true in matrilineal societies, where children usually grow up with their maternal kin. It could also be argued that contemporary Western societies may provide a good base for the study of grandparental investment behavior because they lack clear patrilocal or matrilineal living arrangements (Tanskanen and Danielsbacka 2018). In these societies, individuals can commonly choose the relatives with whom they are willing to interact.

Sex of a Grandchild

During recent years, several evolutionary studies have asked, "Does the sex of grandchildren bias the investments by grandparents?" Genetic relatedness between biological grandparents and grandchildren is, on average, 25%. Because of the asymmetric inheritance of X and Y chromosome, the relatedness actually varies between 23% and 27% (Euler 2011). According to X chromosome relatedness, maternal grandmothers are 25% related to both grandsons and granddaughters, while paternal grandmothers are 0% related to grandsons and 50% related to granddaughters. Relative to Y chromosome relatedness, maternal grandfathers are 0% related to both granddaughters and grandsons, while paternal

grandfathers are 0% related to granddaughters and 100% related to grandsons.

According to the inclusive fitness theory (Hamilton 1964), increased genetic relatedness between kin is associated increased investment. According to this logic, there should be no differences based on the sex of grandchildren in the case of maternal grandparents. In contrast, it could be predicted that paternal grandmothers invest more in their granddaughters than grandsons, while paternal grandfathers invest more in their grandsons than granddaughters. A handful of studies have tested the X and Y chromosome relatedness predictions using data from contemporary societies (Chrastil et al. 2006; Tanskanen et al. 2011). These studies have not, however, found convincing support for the hypotheses. Thus, it could be that paternity uncertainty overrides any X or Y chromosome effect in present-day societies.

Outcomes of Grandparental Investment

Quantification of grandparental investment is not always easy, making it difficult to assess how the importance of grandparental investment has changed through time. In traditional and historical societies (i.e., natural fertility and mortality populations), the importance of grandparental investment in grandchildren is often harder to quantify than it is for contemporary societies. While current surveys can directly ask those giving and receiving care about the nature of investment, this is notably absent from historical records. In traditional and historical populations, the presence of older parents in the same household or in the same village as adult children has been used as a proxy for grandparental investment because when older parents live closer to their descendants, they also have a higher probability to invest (Sear and Coall 2011).

Existing research indicates that in traditional and historical populations, grandparental presence has often been associated with increased female fertility (Sear and Coall 2011). According to an extensive review, the presence of mothers was associated with increased female fertility in

7/12 studies, the presence of fathers in 5/8 studies, the presence of mothers-in-law in 4/6 studies, and the presence of fathers-in-law in 3/5 studies. Additionally, mother presence was associated with decreased female fertility in two studies. Overall, in nearly 90% of populations, the attendance of at least one parent or in-law was associated with fertility.

During recent years, an increasing number of studies have detected whether grandparental investment (e.g., childcare or emotional support grandparents provide to their adult children) is associated with parental fertility in contemporary Western societies. Although several studies have found that grandparental investment is associated with improved fertility, others have not detected such an association (Tanskanen and Danielsbacka 2018). These mixed results indicate that in contemporary affluent societies with public support to families, grandparental investment could not be as important for fertility compared to traditional and historical populations.

There is also evidence showing that, in traditional and historical populations, grandparental presence has been associated with improved child survival. Based on a review of the existing literature, maternal grandmother presence was associated with increased child survival in 9/13 studies, paternal grandmother presence in 9/17 studies, maternal grandfather presence in 2/12 studies, and paternal grandfather presence in 3/12 studies (Sear and Mace 2008). Furthermore, paternal grandfather presence was correlated with decreased child survival in 3/12 studies (Sear and Mace 2008).

In contemporary Western societies with low rates of childhood mortality, grandparents are not needed to keep their grandchildren alive compared to traditional and historical populations. However, it is argued that grandparents can still benefit their descendants when measured by “softer” outcomes, for instance, child development and psychological well-being (Sear and Coall 2011). Several studies have shown that grandparental investment is associated with increased grandchild well-being in particular, during family crises, such as parental divorce, severe illness, or even death, although it is unclear

whether grandparental investment causally improves child well-being in present-day societies (Tanskanen and Danielsbacka 2017). Hence, in traditional and historical populations, grandmaternal presence may have had a positive influence on child survival, while the presence of grandfathers may have no effect or may even have a negative effect.

Finally, it is assumed that the asymmetric inheritance of X chromosomes may bias the grandparental effect, meaning that granddaughters and grandsons survive differently with the presence of maternal and paternal grandmothers. According to a review of previous studies, in 7/7 studies, boys were found to survive more probably with maternal than paternal grandmothers, and in 6/7 studies, girls were detected to survive more likely than boys with paternal grandmothers (Fox et al. 2010). Nonetheless, in only 4/7 studies, girls were found to survive more probably with paternal grandmothers than maternal ones, which was in contrast with the theory (Fox et al. 2010). Additionally, a more recent study from historical Finland showed only limited support for the effect of X chromosome relatedness (Chapman et al. 2018). These findings indicate that an alternative explanation for the potential grandparental effect is needed.

Conclusion

Grandparental investment tends to vary according to genetic relatedness, sex, and lineage. Biological grandparents typically invest more than non-biological grandparents, and maternal grandmothers invest the most and paternal grandfathers the least. Studies concerning traditional and historical populations have used grandparental presence in the same household or village as a proxy for investment. Several studies have shown that in these populations, grandparental presence has been associated with both increased parental fertility and improved child survival. Studies from contemporary Western societies have shown that grandparental investment is often associated with child well-being, although it is unclear whether the association is causal. Studies detecting

associations between grandparental investment and parental fertility have provided mixed results. Although grandparents tend to be highly involved in their grandchildren's lives in different societies, the outcomes of grandparental investment may vary substantially.

Predictors of Infanticide

Alita Cousins

Psychology Department, Eastern Connecticut State University, Willimantic, CT, USA

Synonyms

Filicide; Neonaticide; Progenicide

Definition

Infanticide is the intentional murder of a child under one year of age.

Introduction

One of the fundamental principles of evolution is that traits that enhance the survival and reproductive success of an individual are passed to offspring. Over time traits that have a selective advantage may become adaptations. These adaptations serve a special purpose and are designed to solve problems of survival and reproduction (Buss 2015). Infanticide is the intentional murder of a child under one year of age (Marks 2009). On the surface, murdering an infant seems like an evolutionary conundrum. That is, it seems to violate the idea that adaptations enhance reproductive success. The question becomes, can infanticide have an evolutionary function? Can it ever be beneficial to kill one's own child? This section will address predictors of infanticide and whether infanticide may be an adaptation.

Seminal research by Martin Daly and Margo Wilson (1980) addressed discriminative parental solicitude, the idea that parents vary in how much they invest in a particular child. There are circumstances in which parents benefit by investing heavily in offspring, but there are also circumstances in which parents do not benefit from heavy investment. The “payoffs” for investment vary for different individuals due to a number of factors, and investment can range from high levels to neglect, abuse, and sometimes murder (Daly and Wilson 1980). Evolutionary psychologists studying discriminative parental solicitude believe that low investment may be beneficial to some parents in terms of their overall survival and reproductive success, and it may even function as a form of intrasexual competition between women (Cousins and Porter 2017). As Martin Daly and Margo Wilson (1988) so elegantly put it, “Infanticide can be the desperate decision of a rational strategist allocating scarce resources” (p. 42).

Biological Parents vs. Stepparents

The first hours of a child's life are often the most precarious, partially because this is the most likely time when a child will be killed. In fact, research indicates that 45% of children that are murdered are less than 1 day old (d'Orban 1979). Historically this was also true. In Finland in the 1850s, 95% of infanticides involved children less than 24 h old (Koskivirta 2017). Canadian homicides records (1974–1983) indicate that younger children, especially those under 1 year of age, have a much higher risk of being killed by a biological parent. In comparison, when children are killed by individuals who are not related to them, the risk becomes higher as the child becomes older (Daly and Wilson 2008). From an evolutionary perspective, this makes sense. As parents invest more in a child, that child becomes more valuable to them. This occurs because the heavy investment in the child cannot be returned, so an evolutionary perspective predicts that parents should cease investment as soon as possible. During the first week of life, biological mothers are the most likely person to kill an infant (Marks 2009). Infanticide in this time period may be a function of the mother assessing whether she is capable of the high level of investment necessary to raise a child. Although fathers may invest heavily in children, their investment early on was less than women's due to women having to breast feed an infant (more on this later). Between 8 days old and 12 years old, biological mothers and fathers are equally likely to kill a child (Kunz and Bahr 1996).

Although biological parents are frequently the perpetrators of infanticide, stepparents are statistically even more likely to kill children. Compared to children living with two biological parents, children living with one biological and one non-biological parent – usually a stepparent – are up to 100 times more likely to be killed (Daly and Wilson 2008). The difference in rates of homicide between biological and non-biological parents makes sense in terms of evolution: biological parents reap much higher rewards for investment in children because those children share 50% of their genes. Stepparents, however, do not share any genes with their stepchildren, and therefore

the benefits for investing in them are lower. This is particularly true for the youngest children, who require much more care over a longer period of time. Research shows that the youngest children living with one non-biological parent face the highest risk of homicide, especially children under the age of two (Daly and Wilson 2008).

Discriminative Parental Solicitude, Life History, and Infanticide

For human females parenting is very costly in terms of time and resources needed to successfully raise a child. Due to internal fertilization and gestation, women can only produce one child every 9 months at a maximum. Figures from hunter gatherers show that fertility is surprisingly low despite not using contraceptives. Among the Hadza, the mean number of offspring is 6.1 (Blurton Jones 2016). The !Kung have even lower fertility with a mean of 4.7 offspring, while the Ache have slightly higher fertility at 8.0 offspring (as reported in Blurton Jones 2016). Although there is variability in these natural fertility populations, all these populations have very low numbers of children considering they do not use contraceptives. While a man's ability to produce offspring is only limited by the availability of fertile women willing to mate with him, menopause is a barrier to producing high numbers of offspring in women. By the time a woman reaches her mid-forties, her chance of conception is very low. Among the Hadza, the median age at last birth was 40 (Blurton Jones 2016). Prior to the modern invention of formula, women would have needed to breastfeed a baby for an extended period of time. Research shows that in traditional societies, women breastfed for just over 30 months on average (Kelly 1995). Based on this number, pregnancy and lactation may have required an additional 100,000 calories above what is normally necessary. Although some women may not choose to invest this heavily in each child, higher investment increased the odds that a child survived early childhood (Hrdy 1999). How much or little women breastfeed may be one indicator of the payoff for investment in offspring. For some women heavy investment in terms of maternal lactation and care had higher payoffs; other

women simply cannot afford the high price of this sort of investment (Hrdy 1999). There are a range of options these women may take. In some cases they kill their child, but sometimes they may simply wean their child early or neglect to care for their child. Discriminative parental solicitude predicts that parents do not always benefit to the same extent from investing in a particular child, and therefore both the quantity and quality of care will differ across predictable circumstances.

When biological parents kill their infants, a number of factors have been shown to reliably predict infanticide. The following sections explore the reasons biological parents sometimes kill their babies.

Low-Fitness Offspring

Across a wide range of cultures, one common reason for abuse and infanticide is a child that is born with an obvious problem (e.g., Lightcap et al. 1982). Twenty-one of 35 societies report infanticide or abandonment of deformed or sickly children (Daly and Wilson 2008). In Japan, disabled children are at higher risk of being killed by their parents (Taguchi 2007). While infanticide is the worst outcome for disabled and sick children, it is not the only potential hazard a child may face. For instance, disabled children are at higher risk for being abused (Hunter et al. 1978). In Brazil, impoverished mothers experience high infant mortality rates, which are partly due to these mothers neglecting infants who are in poor health (Scheper-Hughes 1984). Mothers with few resources may conclude that neglect or infanticide is the only option to save resources for other offspring or to wait and invest in a child born during better circumstances. In fact, across cultures, people often conclude that investing in sick or disabled children will be a hindrance to the parents (Scheper-Hughes 1984).

Mothers' Age

The age of the mother is an important factor in infanticide, with young mothers being the most likely to kill a child (Daly and Wilson 2008; Overpeck et al. 1998). Young motherhood was linked to the greatest risk of intentional fatal injury

in a large study of children in California (Putnam-Hornstein 2011). Research shows that the youngest mothers, those under age 15, had a rate of infanticide seven times higher than for mothers over the age of 25 (Overpeck et al. 1998). Other research shows that mothers under the age of 20 are more likely to kill their prematurely born infant compared to mothers older than 20 (Luke and Brown 2007) and that the median age of infanticidal mothers was 19 (Herman-Giddens et al. 2003).

Why does age of the mother matter? There are probably several reasons for this, including poverty and lack of paternal support, which are discussed further below. Another reason young mothers are particularly likely to kill their infants may have to do with differences in the costs and rewards of investment in children across a woman's lifespan. One such trade-off women face is between current and future reproduction. This is because energy is finite. Resources spent on reproduction cannot be used for maintenance, such as growth or staying healthy. This is called an opportunity cost (Kaplan and Gangestad 2005). What this means is that reproducing now may bring a cost to future reproduction. Reproducing during the teenage years may have extra costs if the woman is not yet fully matured. For example, a teenage girl may not be fully grown when she becomes pregnant. The pregnancy will hinder her growth, and she will never reach her full height. Young mothers have many more years to reproduce, so delaying reproduction may reap higher rewards compared to reproducing before full maturity. By delaying motherhood to a later time, women do not need to confront the competing demands of pregnancy and growth (Kramer and Greaves 2010). In assessing the Pumé, a South American hunter-gatherer group, researchers found that young women have a very early first reproduction (*Age* = 15.5), but Pumé women put more energy into early skeletal growth and reach full maturity earlier than women in some other hunter-gatherer groups. Therefore, Pumé women do not face trade-offs between growth and investment in pregnancy (Kramer and Greaves 2010). However, in most circumstances, teenage mothers are not fully physically

mature, and investing in a child therefore has a higher cost.

Older women have fewer years of future reproduction, so evolutionary psychology predicts that these women will be more apt to invest in children even when the circumstances are not optimal. This is expected to be especially true if they have no other children because women with other children should put more effort into existing children if circumstances limit a woman's ability to invest in a newborn. This is because older children have already received so much investment that a woman should prefer to invest in an older child, all other things being equal. In addition, older children have passed the very risky infancy, a time when, historically, many children succumbed to disease. Research supports the idea that older mothers should invest more in infants than younger mothers. Older mothers invest more in premature infants than younger mothers, especially when they have no other children (Beaulieu and Bugental 2008). When young women do become pregnant, infanticide may be the only mechanism left for them to limit investment in a child where the costs associated with investing in the infant may impede future reproduction. As stated earlier, infanticide is an action women take when they are in a dire situation and may find themselves in better circumstances in the future.

Paternal Support

Since human infants require so much investment by both parents, some evolutionary psychologists believe that marriage systems may have developed as ways to increase survival of children. It follows that a lack of paternal support decreases offspring survival and may favor lower investment and potentially infanticide, by mothers when they lack adequate help to raise a child alone. This may be particularly true when women are also facing resource scarcity, including living in poverty. Among premature infants, parental separation or other marital problems predicted abuse and neglect (Hunter et al. 1978). Marital problems or unhappiness may be linked with male desertion and therefore may be associated with infanticide. Unpartnered mothers seem

to be especially prone to infanticide. In the early 1800s in Finland, court records show that about a third of all filicides were perpetrated by single mothers, at least in part because of the dire economic circumstances in which these women lived (Koskivirta 2017). In nineteenth-century England, infanticide was particularly prevalent among unmarried women who wanted to maintain high social status; women from lower social groups did not have any social standing to begin with and were reportedly less ashamed by an illegitimate child (Sauer 1978). In Tibet, children often die after parental divorce or when the marriage is unstable. It is difficult to determine if infanticide occurred, but it is likely that even if the mother does not kill her child, her neglect essentially ensures the death of the infant, and this may ultimately increase her fitness by making her more able to marry again because Tibetan women with children from a previous union are not preferred as mates (Levine 1987). In all these cases, young and unpartnered women faced higher costs to raising a child, and therefore infanticide may have been beneficial for these women over a lifetime in terms of her fitness.

Resource Scarcity

Throughout human evolutionary history, resource scarcity was common and meant that women did not always find themselves in circumstances that permitted heavy investment in a child (Daly and Wilson 2008). Humans seem to have a built-in preparation for resource scarcity in the form of anovulation. Very lean women may not ovulate, and there is evidence that female athletes with low levels of fat, such as long-distance runners, are frequently anovulatory (Lunn 1985). Additionally, when women lose weight, they often do not ovulate for a time. Weight loss would have been a good marker of resource scarcity for our ancestors; not ovulating was the best way to prevent a pregnancy from occurring when the ability to invest heavily in a child would be too burdensome. In Nepal, women often lose weight during the monsoon season. Not surprisingly, women are much less likely to ovulate during the monsoon season (38% ovulate) than during the non-monsoon season (71% ovulate; Panter-Brick

et al. 1993). Anovulation is not the only effect of poor circumstances. Live births are also affected by poor environmental conditions. Among the Hadza, during years with extreme weather conditions (e.g., drought), there were significantly fewer live births (Blurton Jones 2016). Lactation has ovulatory suppressing effects even among Western women, and these effects are stronger among lean women and those that breastfeed at night, as is common in traditional societies (Lunn 1985). But what happens when a woman becomes pregnant despite poor conditions?

Resource scarcity is linked with child abuse and infanticide. Babies born prematurely were more likely to be abused if their parents were poor (Hunter et al. 1978). Poor Italian women are more likely to kill their children. Among these women, babies under 24 h old were at much higher risk than older infants and children (Ciani and Fontanesi 2012). To cease investment only for the youngest infants when conditions are not good makes sense because any investment by these women would be a waste of precious resources. In the United States, in those states that have more maternal poverty and lower per capita incomes, there are higher rates of infanticide (Gauthier et al. 2003). In the early 1800s in Finland, poverty was a leading reason for both infanticide and filicide, killing older children. In a study of court cases involving filicide, more than half of cases involved the most desperate parents with the lowest socioeconomic status, and rates of filicide were higher in years when crops failed and after war when there was little to eat (Koskivirta 2017). Poverty was a leading cause of infanticide in England from the sixteenth to nineteenth centuries, too. Not surprisingly, baptismal records indicate that fewer children were baptized when the economy was poor. This was probably due to several related factors: parents may have tried harder to prevent pregnancy, aborted pregnancies were higher, and children born during financial crises were more likely to be killed (Sauer 1978). In terms of fitness benefits to parents, those who ceased investment in children, especially infants, when resources were scarce and surviving childhood was unlikely, would have out-reproduced parents

who invested heavily in children even under poor circumstances.

Birth Spacing

Reliable contraception is a modern invention, although primitive condoms and other devices have been used for hundreds of years (Levay et al. 2015). The need for heavy investment in offspring should have necessitated adaptations that increased interbirth intervals without contraception. As discussed earlier, lactation can increase interbirth intervals by interfering with ovulation, but this is not a fail-safe method, and anovulation is more likely for women who are lean and breastfeed at night (Lunn 1985). Women who have births spaced too closely together may not have adequate resources for two young children. In some cases, it appears that insufficient birth spacing increases abuse and neglect of premature infants (Hunter et al. 1978). Mothers who had at least four other children were more likely to have an infant die, although this study did not show whether the death was due to infanticide (Puffer and Serrano 1973). As stated earlier, neglect is on the spectrum of parental investment and may be a way to divert resources from a child likely to die toward older children for whom the parents have already invested a great deal. There is evidence that among young mothers under age 20, infanticide was more likely if the mother had two children (Overpeck et al. 1998). At such a young age, birth spacing would be an important determinant of infanticide.

Can We Reduce Infanticide?

Although evolutionary theory predicts that a specific set of circumstances is associated with infanticide, can evolutionary psychology be used to reduce infanticide? I believe the answer is yes. Young mothers are more likely to kill their infants, especially when they are poor. Therefore, one suggestion would be to make reliable contraception readily available to these young women at no cost. Research supports that teen pregnancy rates are reduced when contraception is free and comprehensive sex education occurs. For instance, in a prospective cohort study of women who were at

high risk for repeated abortions, women were offered contraception (especially long-acting forms of contraception like implants and IUDs) free of charge. Women who entered this program were less likely to become pregnant as teens and were also half as likely to seek abortions compared to women regionally and nationally (Peipert et al. 2012). Reliable, free contraceptives may also reduce infanticide that is due to short interbirth intervals. Family planning is important in helping women improve the timing of births and access to contraception, especially forms that are long acting and reversible are an important part of making sure that women have children when they feel capable of successfully rearing those children.

Relatedly, comprehensive sex education should be taught in schools. Women need to be empowered to understand both how to use contraceptives and how to speak to partners about using contraception. Research comparing teen pregnancy rates between those who receive comprehensive sex education compared to those who receive abstinence-only education show that there is a reduction in teen pregnancy rates for those who receive comprehensive sex education, but the same is not true for those who participate in abstinence only programs (Kohler et al. 2008).

Resource scarcity is another predictor of infanticide. In industrialized countries resource scarcity is simply another word for poverty. One obvious way to reduce infanticide is to lift people out of poverty.

Finally, living with both a biological and non-biological parent increases infanticide over living with two biological parents. Does that mean a parent should not be allowed to live with someone not related to their child? I do not believe this automatically follows. Historical research assessing two regions during the seventeenth and eighteenth centuries show that after the death of a biological parent, having a stepparent did not necessarily increase child mortality; the environmental circumstances in the region mattered a great deal in determining whether having a stepparent was detrimental for a child after the death of a biological parent. In Québec where resources were plentiful and large families were better able to compete, having a stepfather was better than

having a widowed mother who did not remarry because a widowed mother would not have been able to adequately support a family in that region. Stepmothers had no effect on survival of children in Québec. However, this was not true when competition for resources was high. In the Krummhörn, where competition was high during this time period, having a stepmother increased child mortality. Stepmothers probably favored their own biological children at the expense of stepchildren living in the household and because resources were scarce, and competition was high, this meant that stepchildren were more likely to die. Overall stepfathers in the Krummhörn had no effect on child mortality (Willführ and Gagnon 2013). What this research shows is that investment in stepchildren is altered depending on environmental circumstances. Sometimes it is beneficial to have a stepparent, at least compared to having only one parent that has been widowed.

Conclusion

It is clear from cross-cultural, historical, and modern research that infanticide has been relatively common. Predictors of infanticide are young motherhood, lack of paternal support, resource scarcity, close birth spacing, and offspring that are sickly or have a clear physical problem. In addition, children living with non-biological parents are statistically more likely to be killed than those living with two biological parents. All these predictors of infanticide make evolutionary sense, and it appears that infanticide is an extreme solution for people facing poor outcomes; it may be an adaptation. However, evolutionary psychology may also be used to mold policies that, in particular, improve family planning and therefore could result in a reduction in infanticide.

Predictors of Sexual Debut

Shaina Trevino and Atika Khurana
University of Oregon, Eugene, OR, USA

Synonyms

First intercourse; Sexual initiation; Sexual onset

Definition

The age at which an individual initiates vaginal sexual intercourse.

Introduction

Human behaviors are regarded as either adaptive or maladaptive depending on the degree to which they promote or undermine health. Early sexual debut, typically defined as the initiation of vaginal intercourse before the age of 14, is associated with increased likelihood of multiple and risky sexual partners, as well as long-term negative health consequences like unintended pregnancies and sexually transmitted infections (Sandfort et al. 2008). Given the costs associated with these outcomes, most research has viewed early sexual debut as a problem behavior that should be prevented. This view, however, fails to account for evolutionary drives, such as reproductive success, that may be especially useful in understanding predictors of sexual debut in adolescents. Adolescent behaviors that are viewed as “risky” from a developmental psychopathology lens (Cicchetti 1989) can be adaptive for the individual if the anticipated benefits outweigh expected costs in relation to genetic fitness (i.e., reproductive success). Recognizing the adaptive functions of sexual behaviors across social contexts is crucial to understanding variations in sexual debut (i.e., early vs. late) and developing interventions that do not contradict individual’s goals and motivations for sexual activity (Ellis et al. 2012).

Theoretical Perspectives

Life History Theory (Roff 1992; Stearns 1992) posits that natural selection has favored biological mechanisms that allocate energy and resources to maximize potential benefits in relation to costs in differing ecological conditions. Thus, when individuals make decisions based on attaining a greater reward in one domain, it comes at the expense of missing out in another domain. For example, biological resources expended on growth and development cannot be invested on reproduction and child rearing. In the case of timing of sexual debut, individuals, given their ecological context, choose between a longer childhood and its associated costs and benefits versus early child rearing and its costs and benefits. These life decisions over time accumulate into differing trajectories, termed as life history strategies.

Building on the Life History Theory, the Psychosocial Acceleration Theory (Belsky et al. 1991) suggests that familial and ecological stressors (e.g., poverty, harsh parenting) can lead to an accelerated developmental trajectory in children, including a fast, quantity-oriented reproductive strategy with accelerated pubertal maturation, earlier sexual debut, and a tendency to form short-term, unstable social bonds. In contrast, children exposed to stable and supportive familial and ecological conditions develop quality-oriented reproductive strategies. Delayed pubertal and sexual onset, and eventually, formation of stable pair bonds, and increased parental investment (i.e., fewer offspring and more resources expended on children; Belsky 2012) are adaptive goals for children growing up in resourceful stable environments. In both cases, the development is adaptively adjusted based on local conditions.

Sex Differences

According to the Sexual Selection Theory (Trivers 1972), males and females need to solve different adaptive problems during development and therefore, are expected to have varying predictors of sexual debut leading to different adaptive reproductive strategies. For example,

earlier pubertal timing is a strong predictor of earlier reproductive strategies for females, whereas, peer status and intrasexual competition (e.g., possessing characteristics that make them attractive to mates and successful in same-sex competition) are more predictive of sexual debut for males. Sex differences in the role of perceived mate value was highlighted in a recent longitudinal study of 12–18 year olds which found that higher perceived mate value partially mediated the effect of early pubertal maturation on sexual debut, but only in case of males (James et al. 2012).

In case of females, fathers can play a unique role in predicting sexual debut that is separate from the effects of mothers or other environmental stressors. The quality of paternal investment in child rearing has varied across evolutionary history, and this variation has repeatedly influenced survival and reproductive success (Draper and Harpending 1982; Ellis 2004). A number of studies have found that females whose biological father was absent from the home during childhood tended to have earlier pubertal timing (Alvergne et al. 2008; Webster et al. 2014), and earlier sexual debut (Ellis et al. 2003; James et al. 2012), as compared to their female counterparts who grew up with their biological father present.

Family stressors also tend to have a larger effect on pubertal development and sexual debut in the case of females. In a prospective study of 120 children followed from infancy (12 months) to 5th grade (age 11), Ellis and Essex (2007) reported that for females, nonsupportiveness in the family during preschool was associated with earlier pubertal status at the age of seven, and subsequent earlier maturation of secondary sex characteristics in the fifth grade. Family stressors did not impact pubertal or sexual maturation in males. Others have found similar results with female adolescents (ages 9–16) with histories of maltreatment, who achieved pubertal maturation 8 months earlier than nonmaltreated females (Costello et al. 2007). Additionally, Belsky and The NICHD Early Child Care Research Network (2010) found that greater maternal harshness as early as 5 years of age predicted sexual risk-taking (i.e., frequency of oral and vaginal sex, sexually

transmitted infections, and pregnancies) at age 15 in females, and this effect was fully mediated through earlier pubertal timing. Relatedly, other longitudinal studies have found that the effect of childhood stress (i.e., parental absence, parental depression, low socioeconomic status) on sexual debut is partially mediated by pubertal timing for females, but not for males (James et al. 2012). These observed sex differences suggest that males and females may have differing evolutionary motivations and mechanisms for engaging in earlier or later sexual debut.

Environmental Predictors

Unpredictable and harsh environmental conditions have consistently been linked to faster life history strategies (Belsky 2012; Brumbach et al. 2009; Ellis and Bjorklund 2012). In harsh environments (e.g., heightened risk of dying), internal mechanisms have evolved to accelerate development in order to increase the chance of reproducing before death. Similar processes are at work in unpredictable environments. If an individual is unable to predict their future or foresees a bleak future, then having a slower, quality-focused reproductive trajectory may not pay off in the long run. Thus, exposure to harsh and unpredictable environments lead individuals to develop a “I need now – I can’t wait” attitude, and thus, increasing their likelihood of earlier sexual debut (Belsky 2012). Specifically, in terms of sexual initiation, some longitudinal studies have found that children who experience more harsh and unpredictable environments in early childhood (between ages 0–5) have an increased tendency for earlier sexual debut, for both males and females (Belsky et al. 2010; Ellis et al. 2012; Simpson et al. 2012).

Exposure to early stress is one mechanism by which early rearing environments can influence pubertal maturation and sexual debut. Developmental systems have evolved in order to adapt to the level of stress in the environment. Stressful environments do not necessarily interrupt development, but regulate it towards adaptive behavioral and functional processes that have been

successful in stressful conditions throughout evolutionary history (Ellis et al. 2012). Although these strategies may be evolutionarily adaptive in the moment, they can nonetheless be harmful to the individual in long run or damaging to the society (Ellis and Bjorklund 2012).

The effect of both supportive and stressful environments on life history strategies has been shown to be mediated by attachment security (Belsky 2012). Development of secure attachments during childhood has been linked to slower reproductive strategies (i.e., delayed sexual debut) (Miller and Fishkin 1997). According to Psychosocial Acceleration Theory, the main evolutionary function of the first 5–7 years of life is to instill a sense of understanding about the availability of resources, the trustworthiness of others, and the stability of close relationships – all of which affect an individual’s reproductive development and strategies. Attachment security plays a key role in the development of a child’s sense of trustworthiness and orientation towards others (i.e., manipulative vs. altruistic). The theory posits that exposure to adverse rearing environments (e.g., lack of resources, negative parenting styles) leads to the development of insecure attachments and mistrust in relationships, which accelerate pubertal development and results in earlier sexual debut (Belsky et al. 1991). Insecure infant attachment as early as 15 months of age has been associated with earlier pubertal timing (Belsky et al. 2010). Thus, attachment insecurity can influence early sexual debut both by impacting biological processes like pubertal timing but also by making it more challenging for individuals to develop and sustain long-term relationships that increase reproductive success.

Reproductive strategies (i.e., early vs. late sexual debut) are also differentially affected by the environmental contexts. Biological processes (e.g., genetics, physiological reactivity) function as susceptibility mechanisms that can moderate the effect of environmental influences on reproductive strategies (Ellis and Bjorklund 2012). Biologically susceptible individuals are more likely to experience lasting developmental changes resulting from positive (e.g., abundant resources and support) and negative environmental experiences (e.g., heightened stress and

adversity) as compared to less susceptible individuals (Belsky 1997). In an empirical test of this hypothesis, Ellis and colleagues found that in a sample of 120 children who were followed from preschool (ages 3–5) through grades 3–9 (ages 9–17), lower-quality parent-child relationships during the preschool years predicted earlier pubertal timing and quicker sexual maturation. However, these effects were only significant for children with heightened biological sensitivity to environmental contexts, as assessed through the child's physiological reactivity to standardized stressors (i.e., parasympathetic and sympathetic activation, and cortisol levels) (Ellis et al. 2011).

Conclusion

Human developmental processes are evolutionarily designed so that biological mechanisms are differentially expressed in response to environmental contexts. Female reproductive strategies seem to be more sensitive to familial and ecological factors, whereas male reproductive strategies tend to be more sensitive to peer influences (Belsky 2012). In both cases, environmental factors (e.g., stress, unpredictable and harsh conditions, and social status) adaptively calibrate biological mechanisms (e.g., pubertal timing), which subsequently leads to variation in sexual debut. Understanding the evolutionary function of sexual behavior is necessary to inform interventions that do not contradict individual's goals and motivations for sexual activity (Ellis et al. 2012).

Definition

The physical and psychological traits that men prefer in their romantic partners and how these preferences differ between short-term romantic relationships and long-term romantic relationships.

Introduction

From an evolutionary perspective, men are expected to possess a set of mate preferences

that are adaptively adjusted and calibrated based on whether they are pursuing short-term or long-term mating. Evidence reveals that men's preferences do change in predictable directions based on their operative mating strategy: Preferences for cues of fertility and sexual accessibility take priority in short-term mating, whereas preferences for cues of reproductive value, health, and pleasant personality traits take priority in long-term mating. It is important to note that natural selection shapes motivational systems. Given that many of these motivational systems operate below conscious awareness, men may not be cognizant of their mate preferences nor their effects on men's fitness.

Men's Preference by Mating Context

Sexual Strategies Theory (SST) is the overarching theory that explains the adaptive significance of mating strategies in humans (Buss and Schmitt 1993). According to SST, a fundamental asymmetry in obligatory investment in reproduction (i.e., gestation) led men and women to evolve somewhat different mating psychologies: men are more interested than women in short-term mating, and women are more interested than men in long-term mating, on average. That said, most men and women pursue a range of mating strategies at some point in their lives. For example, many individuals might engage in short-term mating earlier in life, then transition to long-term mating later in life. The most common way to assess an individual's current mating strategy is to administer the revised sociosexual orientation inventory (SOI-R; Penke and Asendorpf 2008). Higher scores on the SOI-R indicate a stronger orientation toward short-term mating, and consistent with SST, men score significantly higher than women on this scale.

Short-term mating. Men who pursue short-term mating strategies increase their reproductive success by maximizing the number of fertile women to whom they gain sexual access. Men possess a number of psychological adaptations that facilitate this strategy, such as a desire for a variety of sexual partners, requiring less intimacy

before engaging in sexual contact, and erring on the side of false alarms rather than misses with regard to sexual approach behavior. In addition, men's mate preferences generally become relaxed in short-term mating to facilitate the accrual of additional mates; however, men increase their preferences for cues of sexual accessibility and fertility, traits that increase men's likelihood of reaping the reproductive benefits of short-term mating.

There are many factors that influence how selective a man will be in his mate choice (e.g., his mate-value, the local sex ratio), but pursuit of a short-term mating strategy is arguably one of the biggest influences. A successful short-term mating strategy rests on enlarging one's pool of potential mates, as each additional mate has the potential to increase a man's reproductive success. Less selective men, quite simply, have more options than choosy men. In many categories of mate preferences, such as intelligence and kindness, men show decreased selectivity specifically for sex partners but not for long-term mates (Kenrick et al. 1990).

As men pursuing short-term mating opportunities become less selective for many traits, they become more selective for certain traits that predict a woman's ability to increase their reproductive success. One such example is men's greater desire for sexual accessibility. Men pursuing short-term mating are more likely to find targets who display cues of easy sexual access to be desirable (Schmitt et al. 2001). Even if a woman does not show cues of overt accessibility, men might also look for signs that the woman is exploitable via persuasion or other means. Men do in fact find cues that a woman is exploitable to be sexually attractive, specifically as a short-term mate (Goetz et al. 2012).

Another set of traits that are particularly important for short-term oriented men are those predictive of a woman's underlying fertility. Because fertility is not directly observable, men rely on certain cues that have been recurrently correlated with women's fertility over evolutionary history. One of the clearest cues of fertility is a woman's waist-hip ratio (WHR; ► [Waist-to-Hip Ratio](#)) in that it tracks underlying estrogen levels and is

associated with ease of becoming pregnant, as well as a host of other positive health outcomes. The estrogen-dependent nature of WHR makes it a reliable indicator of whether a woman has reached sexual maturity (i.e., postpubescence) and is premenopausal. WHR also provides cues to whether a woman is pregnant – a condition of temporary infertility – as her WHR steadily increases as her pregnancy progresses. Finally, there is evidence that WHRs might slightly decrease at ovulation, the point in a woman's menstrual cycle at which she can become pregnant. Ovulating women are particularly attractive to short-term mating men for this reason (Men's Preference for Ovulation), whereas men pursuing long-term mating need not capitalize on a single ovulation given that they are likely to be with their partner for many future ovulations. Consistent with this body of research, studies show that women with relatively low WHRs (i.e., curvier women) are viewed as more attractive than their high WHR counterparts.

Given WHR's influential role in assessing fertility, it is perhaps unsurprising that men who are oriented more toward short-term mating tend to express greater interest in viewing a woman's body than her face. Several studies have now shown that men oriented toward short-term mating, and men experimentally assigned to consider a female target as a short-term mate, tend to pay more attention to a woman's body and spend more "mate dollars" improving a woman's bodily attractiveness than long-term mating men (for a review, see Cloud and Perilloux 2014).

Long-term mating. Men who pursue long-term mating strategies increase their reproductive success by committing themselves to (usually) one woman at a time and heavily investing in any resulting children. Research shows that in the pursuit of a long-term mate, men are just as selective as women (Kenrick et al. 1990). This follows from SST: In long-term mating, each partner's reproductive success is dependent upon the cooperation of another individual (e.g., providing reliable childcare, protection, and resources). Thus, poor mate choice in a long-term relationship can be extremely detrimental for both men and women. Consistent with this logic, cross-cultural

studies show that men (and women) prioritize traits such as kindness, intelligence, and an exciting personality in their long-term mates, probably because these characteristics help maximize compatibility and thus continued reproductive success with a single partner (Buss 1989). A related trait that becomes especially important for men in long-term relationships is a partner's faithfulness (Buss and Schmitt 1993).

One of the key adaptive problems faced by long-term mating men is to avoid accidentally investing in offspring that are not genetically related (i.e., cuckoldry). One solution to this adaptive problem appears to be the emotion of sexual jealousy (Buss 2000), but another solution is a preference for mates who are unlikely to engage in infidelity. This is clearly a probabilistic judgment, but one of the best predictors of extra-marital sexual permissiveness is premarital sexual permissiveness (Thompson 1983). Preferences for complete chastity before marriage, however, are highly variable across cultures (Buss 1989); therefore, men might rely more on cues to future faithfulness (e.g., ignoring advances from rival men, general sexual permissiveness) rather than chastity per se, when evaluating long-term mates.

Assuming fidelity on the part of his mate, one potential benefit for a man in a long-term relationship is continued sexual access. But this benefit only increases his reproductive success if his mate is capable of bearing children – ideally, for years to come. Thus, men in long-term relationships seek mates who have high reproductive value (i.e., those far from the end of their reproductive lifespan). Indeed, research shows that as men age, they prefer mates who are increasingly younger than they are (Kenrick and Keefe 1992), and the age gap tends to increase with each subsequent marriage (Low 1991). Men are also attracted to certain traits associated with youthfulness, such as a high energy level and a lively gait (for a review, see Sugiyama 2005).

Research on the relative importance of a potential mate's facial and bodily attractiveness reveals an interest in viewing a woman's face among men dispositionally orientated toward long-term mating and those experimentally assigned to consider

a female target as a long-term mate. This pattern of results is consistent with the premise that cues of youth – and hence, reproductive value – are more densely concentrated in a woman’s face (e.g., absence of wrinkles) than in her body.

Future directions. Even though much is known about how men’s mate preferences differ across mating strategies, less is known about the transitions many men make from a short-term mating strategy to a long-term mating strategy, or the reverse, over the lifespan. Relatedly, most researchers have focused on short-term and long-term mating as separable strategies, when in reality short-term and long-term mating motivations, if not behaviors, might exist on a continuum with some men pursuing both mating strategies simultaneously (e.g., having a short-term sexual encounter while married or searching for a life partner while having sex with many women along the way). Research designed to address these issues should provide evolutionarily minded scholars with a more nuanced understanding of men’s mating strategies.

Conclusion

Men’s mate preferences adaptively calibrate to short-term and long-term mating strategies. These changes reflect the output of evolved psychological mechanisms that adaptively motivated behavior, conditional on mating strategy, in ways that tended to increase men’s reproductive success over human evolutionary history. Men tend to possess high standards for long-term mates, revolving around personality, compatibility, and reproductive value, whereas men tend to lower their standards for short-term mates, with specific exceptions for traits indicative of sexual accessibility and fertility.

Pregnancy Complications

Deblina Roy
Department of Psychiatry, King George's Medical University, Lucknow, UP, India

Definition

According to CDC, the complications of Pregnancy are disorders and issues that impact the pregnancy in an adverse manner, leading to adverse outcomes of pregnancy for the mother and the fetus. These include, presence of anemia, previous C-section delivery, Cephalo-pelvic disproportion, advanced age, elderly or young primigravida, Rh-negativity, grand multi parity and other, hormonal disorders etc.

Introduction

Pregnancy is a life-changing experience. It is also considered as a very enthralling experience of women's life. Pregnancy brings about a lot of changes in physiology and psychology of the women. Usually pregnancies are predictable and progress according to a set pattern through the trimesters, but almost up to 15% of all pregnancies go through some or the other complications (WHO et al. 2017). This entry will briefly discuss the various complications that may arise and their management.

Objectives of the Chapter

pregnancy can be complicated in many cases and due to presence of various risk factors. There are various conditions which can predispose the women for those complications. The common complications of pregnancy with their management strategies are documented as follows.

Pregnancy with Previous Caesarean Section

Definition

Caesarean section is a common practice in modern obstetrics, as it is used in many deliveries for non-recurrent indications and often as a lifesaving procedure for both mother and child. A pregnancy after delivering by caesarean section is called post-caesarean pregnancy (Dutta 2004).

Impact of Complications on the Outcome

Usually a previous C-section (caesarean section) does not essentially change the course of pregnancy but heightens the risk of the developing some complications (O'Neill et al. 2014).

Complications During Pregnancy and Postpartum

The most common complications associated with previous C-sections include:

Preterm labor (delivery before the term, i.e., 37 weeks of gestation)

Abortion

Placental abnormal position and nature (*placenta previa* and *placenta accreta*) (*placenta previa*: attachment of the placenta in the lower uterine segment rather than the upper body of the uterus) (*placenta accreta*: infiltration of the chorionic villi deeper through the myometrium into serous and neighboring structures)

Increased operational interference and incidental morbidity

Postpartum hemorrhage (excessive bleeding after the birth of the baby more than 1500 ml)

Peripartum hysterectomy (removal of the uterus after the childbirth and related causes)

Effects on the Scar

The previous scarring of the uterus may impact the pregnancy in a unpredictable way. The risk or rupture of scar as there is about 0.2–0.5% chance for rupture of scar in the lower segment and usually may happen during labor, that can lead to life-threatening complications. In case of a classical hysterotomy, scar has a 4–9% chance for rupture in the late pregnancy and during Labour (Jacob 2012:68; Dutta 2004).

Effects on the Healing Wound

The previous caesarean section brings about the chances of difficulty in the wound healing as there may be chances of infection, excessive stretching of the lower uterine segment. The healing happens best when the tissues are apposed in the correct manner. Poor general health may lead to poor wound healing, leading to a weak scar (O'Neill et al. 2014).

Diagnosis

The risk for scar dehiscence can be determined by the following factors:

1. Type of scar: usually a lower segment scar is able to withstand better compared to the classical C-section scar. Due to factors such as angular pull during the growth of the uterus and during contractions of labor. In the

classical C-section, there are increased chances of trophoblastic infiltration (placental tissue) near the scar making it weaker.

Management

Elective C-Section

Previous C-section pregnancy complications can often be managed by delivering the baby by elective C-section in the following pregnancy. Pregnant woman should be admitted in the hospital in the 38th week and plan for surgery. Patient should not wait till the labor pains start.

Emergency C-Section

Whenever there is labor and risk for scar dehiscence, patient should be immediately prepared for OT, and emergency C-section should be done to prevent complications in the mother and the child.

Vaginal Birth After Caesarean Section

In about 70% cases, vaginal birth is successful after a previous C-section delivery (Dutta 2004), but in case of suspected maturity, a C-section delivery is advisable. There are a few benefits of having a vaginal birth after caesarean section. If done under supervision of a team of doctors and skilled professionals, one has lesser maternal mortality, lesser need for a blood transfusion, and better recovery time for mother and adequate care of newborn. There are also risks associated with this; they are risk for scar dehiscence and risk for fetal distress, postpartum hemorrhage, loss of baby, and maternal mortality (Dutta 2004).

Vaginal birth after caesarean section trial of labor (VBAC-TOL) should only be done if the pregnancy was uneventful, and onset of labor was spontaneous with good effacement and dilatation of the cervix, along with constant fetal monitoring. The hysterotomy scar dehiscence (breakage) has about 0.2-0.5% chance and the risk is greater in case of the scarring at the lower uterine segment. this may happen during precipitated labour (Dutta 2004; Myles et al. 1993; WHO et al. 2017).

Pregnancy in RH-Negative Women

Rh factor is an antigen found the RBC of humans and some other primates. This antigen determines the reaction of the blood to negative antibodies and can lead to a hemolytic reaction.

Incidence: Rh-negative people in Europe consist of 15–17%, and there is very less incidence of about 1% in China and almost nil in Japan. Among the Rh-positive, there are almost 40% homozygous and 60% heterozygous in the D locus. Overall chance for a Rh-negative mother to have a Rh-positive fetus is about 60% irrespective of partner's Rh type. The Indian incidence rate is 10% in northern India and 5% in the southern India.

Impact of RH Alloimmunization

The risk for women having pregnancies with Rh-positive partners can lead to the risk for fetal

Rh alloimmunization leading to fetal loss and death. The antibodies (anti-fetal antibodies) can remain in the mother's blood and can create complications for further pregnancies leading to spontaneous miscarriages and abortions (DONOHUE and WAKE 1964) (Fig. 1).

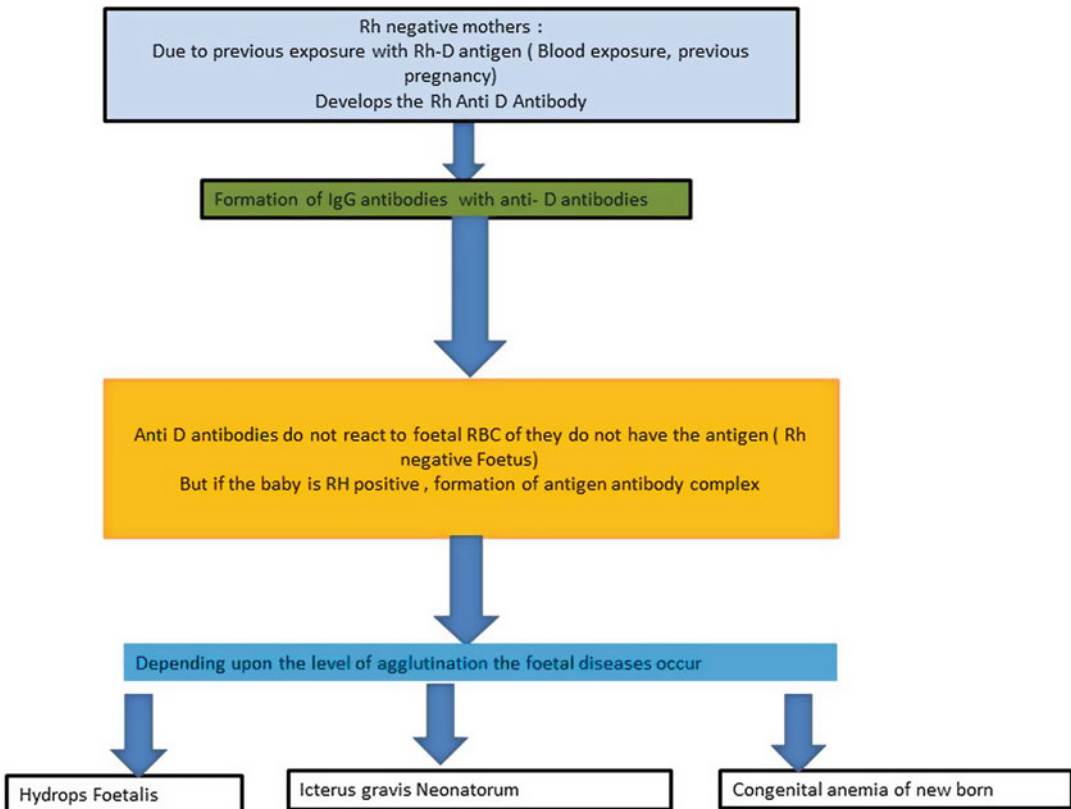

Diagnosis

A test to identify noninvasive fetal genotype (ffDNA) with the maternal blood for D, C, c, E, e, and K antigens could be done to determine the risk for the developing the fetal hydrops.

Management

Include the prevention of active immunization, avoidance of maternal and fetal blood contact, and avoid mismatched transfusion (Donohue and Wake 1964).

During the pregnancy, indirect coombs test every month till the 30 weeks and thereafter

Pregnancy Complications, Fig. 1 Diagram of pathogenesis of red cell alloimmunization

every 2 weeks of pregnancy. Injection Rh anti-D immunoglobulin in previously unimmunized women should be administered to prevent further active immunization; 300 µgm of antibody within 72 h of delivery should be administered at the earliest possible. Cord blood is collected and sent for testing direct coombs test, bilirubin, blood grouping, and cross-matching.

- Exchange transfusion of newborn (Dutta 2004) (the fetal blood is exchanged for unimmunized healthy RBCs for the better survival of the baby. This helps in maintaining the blood volume, preventing anemia, and improving icterus.)

Prognosis: the fetal prognosis depends on the level of maternal antibodies, paternal genotype and fetal genotype, availability of specialized services for care of such cases like NICU, exchange transfusion, etc.

Elderly Primigravida

This is a condition in which a woman usually gets pregnant after the age of 35 years (FIGO), which carries risk for the outcome of the pregnancy. This is a condition in which a woman usually gets pregnant after the age of 35 years (FIGO), which carries a risk for the outcome of the pregnancy. The current age limit of greater than 35 years has been decided arbitrarily by the outcome of pregnancy. It has been observed in the studies that pregnancy after the age of 35 years can lead to greater risk for fetal loss and anomaly. There are two types of elderly primigravida (WHO et al. 2017).

1. High Fecundity: Women who married late and got pregnant soon after marriage (prognosis is good for these women)
2. Low Fecundity: Women who married early on but could not conceive, for a long time, and had to use artificial reproductive techniques to conceive (prognosis is usually poor) (Myles et al. 1993).

Complication

During Pregnancy

The women more than 35 years of age have a higher risk for developing complications including the risk for abortion; deficiencies of folic acid; increased risk for hypertension and preeclampsia; risk for uterine fibroid and other medical complications like pregnancy-induced hypertension (PIH), gestational diabetes mellitus, cardiac the lesion, placenta praevia, and placental abruption due to hypertension; and risk for post-maturity and intrauterine growth retardation of the fetus (Dutta 2004; Jacob 2012; WHO et al. 2017).

During Labor and Delivery

During labor and delivery, there is an increased risk for malposition, malpresentation, preterm labor, prolonged labor, uterine inertia and impaired joint mobility, age-related stiffness in the soft tissue of the birth canal (Allanson et al. 2015) which can lead to poor outcome of the pregnancy, and increased maternal and perinatal mortality.

Fetal Risks

The fetus also has risk for developing congenital malformation, the risk for aneuploidy, and risk for neural tube defects in the fetus (Dutta 2004). This can complicate the pregnancy and impact the outcome adversely, resulting in polyhydramnios pregnancy induced Hypertension and Intra-Uterine death (IUD).

Puerperium

The puerperal period, i.e., the time from after the delivery of the baby to 6 weeks postpartum till the uterus becomes pelvic organ and extended up to 6 months after delivery. After the delivery, there is an increased risk for maternal morbidity as instrumentation and operations are more common and majorly women suffer from pregnancy-related health issues which complicate the outcome for both mother and the child (Jacob 2012).

Perinatal Outcome

Perinatal outcomes are adversely affected by the age factor in both mother and the partner, as with increasing the risk for trisomy 21 (Down's syndrome doubles) (James 2006). The advancing age of the parents and other pre-existing risk factors can increase the complications in the mother and fetus to multiple folds, and the risk for abortion and non-communicable diseases in the child for example; G6PD deficiency, congenital anomalies of internal organs, atrial septal defects, and ventricular septal defects became common giving the caregivers a tough time after the much-awaited childbirth (Myles et al. 1993).

Grand Multipara

Definition

The word grand multipara is a women with pregnancy who already has four or more viable births (Dutta 2004).

Parity

Means the to carry a baby till maturity in the uterus.

Incidence

Due to the small family norm adoption, the incidence of grand multipara has significantly reduced, but till date 1/10 women in the developing countries die due to the complications arising multiple child births. It is still a common cause of live long morbidity not if mortality of women (Allanson et al. 2015).

Complications of Grand Multipara

Pregnancy

Pregnancy of such condition can bring about the risks for:

1. Abortion
2. Iron deficiency anemia (due to draining of the iron reserve of the women due to multiple childbirths)
3. Malpresentation and malposition of the fetus
4. Lordosis loosening of the abdominal muscles

5. Herniation, cardiac disability, hemorrhoids
6. Multiple pregnancies, etc.

Labour and Delivery

Labour and delivery in the complicated cases of pregnancy, as the risk for uterine inertia, cord prolapse, and high-floating head at onset of labor may increase the risk for fetal loss. There is also chance for CPD due to secondary contracted fetus as a result of malnourishment of mothers (Dutta 2004; James 2006; WHO et al. 2017). Rupture uterus may happen as the uterus loses its elastic ability, postpartum hemorrhage, leading to shock and increased operative interference due to presence of complications (Myles et al. 1993).

Puerperium The puerperal period for these mothers becomes very important as they carry the burden of their own care plus the care for the family. The main issues during that period are subinvolution of the uterus, lactation failure, and several infections.

Long-term effects Grand multipara women suffer from some long-term morbidities due to child bearing, most commonly that is developing uterine prolapse and vesicovaginal fistula, recurrent UTI, sexual dissatisfaction, etc. Many women suffer from self-esteem issues due to these complications (Dutta 2004; Jacob 2012; Myles et al. 1993).

Management

Management of grand multipara is done with a few things in mind, the women are screened for the medical and other diseases and put into high risk, and close observation during the pregnancy can help in detecting and diagnosing a lot of problems early on, hence providing the women and her unborn child a way to be safe. There has to be a mandatory hospital delivery in order to prevent any complications (WHO et al. 2017).

Bad Obstetric History

Definition: bad obstetric history can be defined as a phenomenon when the women's current

outcome of pregnancy can be affected by the previous pregnancy disaster history in her life (Dutta 2004).

There are main three *principles of management* of such condition (Allanson et al. 2015; WHO et al. 2017)

1. Identifying the cause of previous related disasters
2. Treating the cause and managing the complications
3. Remaining vigilant till delivery

Etiological factors

1. Thyroid anomalies
2. Hormonal disturbances (PCOS)
3. Anti-phospholipid syndromes
4. Thrombotic disorders
5. Diabetes Mellitus
6. Hyperhomocysteinemia
7. Incompetence of the uterus and cervix
8. Structural anomalies of birth canal
9. Maternal systemic diseases. etc.

Manifestations

1. Recurrent abortions
2. Loss of fetus
3. Congenital anomalies of fetus
4. Weight gain
5. Spontaneous second trimester abortions
6. Cervical incompetence
7. Antepartum hemorrhage, etc.

Anti-phospholipid Syndrome

This condition is associated with the adverse outcome of pregnancy as the vasodilator mechanism occurring for the growth of the placenta and fetus is affected by the anti-phospholipids, leading to chronic placental insufficiency, PIH, placental hypoperfusion, IUGR, and growth failure of the baby (Dutta 2004; WHO et al. 2017).

Inherited Thrombophilia

They are conditions which lead to hyper-coagulability of blood within the blood vessels, and this leads to clotting of blood within the blood vessels.

Management

Assess the offending factor; prevent the factor to cause any more disruption. Provide the best therapy for the pregnant women to continue the pregnancy. Pre-pregnancy folic acid can reduce risk for congenital neural tube defects (Dutta 2004; Jacob 2012).

Vigilance

The care provider and the client have to be very vigilant in such cases, causes should be ruled out, and best practices according to govt. guidelines should be applied to save the mother.

High-Risk Pregnancy

This should be managed mainly by an interdisciplinary team and as an effort and obstetrician, endocrinologist, medical specialist, midwives, etc.

Obesity in Pregnancy

There is no defined criteria for obese in the world, but there is for normal weight, BMI (body mass index) helps us identify the level of obesity. People belonging to 18–24.9 kg/m² are normal and from 25 Kg/m² and above are overweight and people more than 29.9 kg/m². Obesity can bring about a lot of complications in the pregnancy like, gestational diabetes mellitus, HTN (hypertension), dyslipidemia, and many more complications (Murphy et al. 2010).

Effects on Pregnancy

1. Patients feel uncomfortable and have dyspnea on exertion.
2. Medical complications like hypertension, both essential and pregnancy induced, are increased and so also gestational diabetes.

3. There is difficulty in diagnosis of presentation and in hearing the FHS.
4. Macrosomic baby.

Effects on Labor

There is increased incidence of abnormal uterine contraction prolonged labor leading to operative interference and caesarean delivery. Pregnant women who are obese, There is increased incidence of abnormal uterine contraction prolonged labor leading to operative interference and caesarean delivery. There is higher chances of Shoulder dystocia macrosomia obstructed labor and increased risk for birth asphyxia and other foeto-maternal complications.

Puerperium

Postpartum hemorrhage, deep vein thrombosis, infections, fistula and delayed wound healing

Management

Use of planned diet and exercise in maintaining weight is a good way to avoid the complications (Alliance for Maternal and Newborn Health Improvement (AMANHI) mortality study group 2018). Heparin prophylaxis is given to prevent DVT, and mandatory hospital delivery and care in the months of pregnancy should be included. Woman should be counseled on the type of hazards and type of diet to be taken. Weight loss should not be aggressively attempted during pregnancy, but losing the weight and maintaining body weight has its own benefits.

Conclusion

Becoming pregnant and giving birth is a desire among most women. Complications frequently occurring during pregnancy can cause severe distress in them, as well as their immediate family. The knowledge about the pregnancy and related complications can save women their existing forthcoming children from crisis and burden. Timely medical attention can be instrumental in preventing certain complications and limiting their effect on the expecting mother and fetus. The awareness of the complications and their

management strategies can help people develop action plans for such complicated pregnancies. It is a non-negotiable role of the healthcare provider to educate and treat the women with the best practice evidence-based guidelines for a welcome outcome for the women and her forthcoming offspring.

Pregnancy Prevention

► Abstinence

Pregnancy Sickness

Judith Kaiser
University of Bristol, Bristol, UK

Synonyms

[Emesis gravidarum](#); [Morning sickness](#); [Nausea and vomiting in pregnancy](#)

Definition

A collection of symptoms, including food and odor aversions, experienced by pregnant women mostly within the first trimester of pregnancy.

Introduction

Until quite recently, nausea and vomiting in pregnancy (NVP) was viewed as an inconvenient by-product of the significant hormonal changes (hCG, estradiol, and progesterone) that take place during early pregnancy (Forbes 2002), with potential threats to the developing organism due to malnutrition (Pike 2000). However, more recently researchers have cited the adaptive function of pregnancy sickness (Sherman and

Flaxman 2000) on the basis of studies documenting favorable prognostic associations, including the aversions to and cravings of certain foods and improved pregnancy outcomes.

Is pregnancy sickness adaptive?

Pregnancy sickness is associated with approximately 60% of pregnancies (Flaxman and Sherman 2000). The high frequency of pregnancy sickness is puzzling from both a biomedical and evolutionary viewpoint. Given that a pregnant woman has to “eat for two,” why should a condition that limits food consumption take place simultaneously as this dramatic increase in nutritional and caloric demands? This question can be approached from two levels of analysis, proximate (the “how” question) and ultimate (the “why” question). The analysis of any behavior is complete only if both proximate and ultimate explanations are achieved. While most research effort in the field of pregnancy sickness has focused on the proximate mechanisms – that is, elucidating hormonal and psychological correlates of this phenomenon – more recently a discussion has been sparked about whether or not pregnancy sickness serves useful functions (Flaxman and Sherman 2000; Forbes 2002). The importance of this discussion is that it has the power to inform medical practice because it is beneficial to understand what (possibly non-pathological) symptoms were “designed” to do before trying to treat them. In particular, understanding the reasons of why NVP exist can inform us of whether or not it is categorically recommendable to suppress these symptoms (Flaxman and Sherman 2000).

Some researchers have argued that pregnancy sickness does not serve any function. Forbes (2002) has dismissed pregnancy sickness as a simple by-product of mother-embryo conflict over the degree of maternal investment. Women are immunocompromised during pregnancy to secure immune tolerance to the fetus, which the maternal immune system would otherwise reject as a foreign body. Because immunosuppression compromises the mother’s ability to resist

infection while immunoactivity puts the embryo at risk, it is plausible that the optimal level of immunosuppression may differ between the child-bearer and the developing organism. The theory predicts that maternal-fetal conflict will be most intense early in women's reproductive career, because the value of a given fetus depends on the mother's remaining reproductive potential (Forbes 2002). If pregnancy sickness is the result of maternal-fetal conflict, then its severity should be inversely related to maternal age. However, while some researchers report the predicted inverse relationship between NVP and maternal age, others find no association (see Fessler 2002).

Other researchers view pregnancy sickness as harmful. For example, Pike (2000) documented fitness costs (e.g., poorer pregnancy outcomes) associated with pregnancy sickness among a marginally nourished population in Kenya. She concluded that NVP may be maladaptive in resource-poor, low-income, and nutritionally compromised environments. In general, however, not many researchers argue that NVP is maladaptive. In fact, a growing body of evidence highlights the adaptive function of pregnancy sickness. There are two prominent functional theories about pregnancy sickness, the "maternal and embryo protection hypothesis" and the "compensatory placental growth hypothesis," which will both be discussed next.

The "maternal and embryo protection hypothesis" postulates that pregnancy sickness is an adaptation that prevents the intake of substances that could potentially be harmful to both the immunosuppressed mother and the fetus. In the initial formulation of this idea, pregnancy sickness was hypothesized to protect the fetus from embryotoxic substances, like caffeinated and alcoholic beverages. Building on this idea, Profet (1988) embedded the associated appetite changes and benefits into an evolutionary and adaptive framework. She listed the categories of foods that pregnant women might have avoided in our ancestral environment, emphasizing the risk of secondary compounds produced by plants to the fetus. More recently, Flaxman and Sherman (2000) and Fessler (2002) widened the scope to include meat-borne pathogens, fish and eggs. For

instance, *Toxoplasmosis* is an infection caused by a parasite called *Toxoplasma gondii* that can be caught via the consumption of raw or undercooked meat. The infection is typically only harmful to those who have a weakened immune system, as is the case for pregnant women. It can cause abortions or birth defects in pregnant women.

Sherman and Flaxman (2000) have put forward five critical predictions of the embryo protection hypothesis:

Prediction 1

The first prediction is that the NVP should be the greatest when the developing organism and the immunocompromised mother are most vulnerable to infections by pathogens. Organogenesis, the period when the embryo's organs are developing, occurs within the first trimester, and thus intake of harmful foodstuffs is most likely to be harmful at this time. Furthermore, a body of evidence suggests that maternal immunosuppression also peaks during the first trimester, which exacerbates the dangers inherent in this precarious phase. Consistent with prediction 1, several studies have found that, in Western subjects, symptoms of pregnancy sickness are concentrated during the first trimester. The same pattern is documented in numerous preindustrial societies (Fessler 2002).

Prediction 2

The second prediction of Sherman and Flauxman (2000) is that the food items women avoid during pregnancy should contain harmful substances, whereas food items that are craved should not. Sherman and Flaxman (2000), in a meta-analysis of studies examining food aversions and food cravings, discovered that pregnant women most often reported aversion towards food categorized as "meat, fish, poultry, and eggs"; "nonalcoholic beverages" (mostly caffeinated such as tea and coffee); and "vegetables." In line with prediction 2, these three most aversive food categories were the same categories that are high in levels of

potentially teratogenic and abortifacient agents. In contrast, the food categories that were the most craved – “fruit and fruit juice”; “sweets, desserts, and chocolate”; and “dairy” – were also the ones least likely to contain harmful substances. Another study found similar pattern of dietary taboos during pregnancy in many human societies (Fessler 2002). Interestingly, Mckerracher et al. (2015) reported that Yawasa women also developed aversions to their husband’s smell during pregnancy, which they interpreted as an aversive reaction to pathogens carried by their husbands and transmitted sexually.

A few inconsistent findings have been reported. One study of pregnancy sickness and aversions in Tanzania found that pregnant women actually developed food cravings for meat, the same food hypothesized to be principle target of aversions. Another study found olfactory cravings for noxious agents such as cigarettes, ammonia, and bleach (see Patil et al. 2012).

Prediction 3

The third prediction builds upon the second: Pregnancy-related aversions to potentially dangerous foodstuffs should be concentrated within the first trimester. Consistent with prediction 3, Flaxman and Sherman (2000) documented that, in a subsample of their meta-analysis, pregnancy-related aversions to foods peaked in this period and lessened or resolved after that. This finding is complemented by other research showing that pregnant women during their first trimester are significantly more aversive than non-pregnant women towards all food categories, particularly to “meat, fish, poultry, and eggs.”

Prediction 4

If NVP was “designed” as a maternal and fetus protection mechanism, then women who develop NVP should, on average, experience an improvement in pregnancy outcomes over those who do not develop these symptoms. A large body of evidence supports this prediction. Sherman and

Flaxman (2000), in a meta-analysis of nine studies involving 22,305 pregnancies, demonstrated that the risk of miscarriage was significantly reduced for women who developed NVP compared to women who experienced no symptoms. Tierson et al. (1986) divided pregnant women into three categories: (1) those who were asymptomatic, (2) those who only had nausea, and (3) those who developed both nausea and vomiting. The outcome results of this study demonstrated that asymptomatic women were significantly more likely to experience fetal death (20% experienced fetal death) compared to women with nausea only (10.3%) and those with both symptoms (4.3%).

A few researchers have found contradictory evidence. One reported no association between ingestion of certain food types that could cause adverse pregnancy outcomes and symptoms of NVP or pregnancy outcome. Another study did not show a relationship between lack of pregnancy sickness and an increase in the overall rates of major birth malformations (see Patil et al. 2012).

Prediction 5

The fifth prediction is that NVP should be observed less often when the diet consists of foods that rarely contained harmful substances historically. Sherman and Flaxman (2000) analyzed both the diet and frequency of pregnancy sickness in 27 traditional societies. The results of this analysis demonstrated that compared to societies in which NVP was documented, societies without pregnancy sickness were significantly more likely to have maize and/or corn as their main food staples and significantly less likely to consume meat. Consistent with prediction 5, domesticated corn tends to have minimal harmful compounds. Profet (1998) further noted that this corn-based diet is a good source for folic acid, which is a vitamin that reduces the occurrence of neural tube defect.

Taken together, the five predictions of the maternal and embryo protection hypothesis receive a great deal of empirical support, although contradictory findings are also occasionally

documented. Nevertheless, the question arises whether nowadays NVP is simply an evolutionary anachronism since the ingestion of potentially harmful foodstuffs has been significantly reduced through inventions such as the refrigeration and freezing of leftovers. Sherman and Flaxman (2000) argue otherwise. They postulate that the association between NVP and positive pregnancy outcomes in contemporary societies implies that pregnancy sickness remains an important maternal and embryo protection mechanism in the present-day world.

The other major hypothesis put forward to explain the function of pregnancy sickness is the “compensatory placental growth hypothesis” (Huxley 2000). According to this hypothesis, first-trimester nausea and vomiting are an adaptation that lowers maternal nutrient intake that, in turn, suppresses maternal tissues synthesis and promotes placental growth. The symptoms of pregnancy sickness may therefore aid to channel scarce nutrients to the developing placenta. Consistent with the theory, low maternal intake within the first trimester is associated with a larger placenta (Huxley 2000), at least for mild levels of dietary limitations. Based on this hypothesis, it is also predicted that NVP should be observed more frequently in women with high preconceptional body-mass index (BMI; Huxley 2000). However, the findings are inconsistent, with some reporting a higher frequency of NVP in heavier than light women, others finding no relationship, and still others reporting the opposite relationship (see Pepper and Roberts 2006). Overall then, the lack of studies examining or supporting the compensatory placental growth hypothesis makes it difficult to credit it at this stage.

Conclusion

In summary, until quite recently, most clinicians have considered pregnancy sickness as a psychological disturbance of pregnant women. However, recent research suggests that pregnancy sickness serves useful functions. Currently, the front-running functional explanation for pregnancy sickness is that it is an adaptive response that

protects fetal organ development and the immunosuppressed mother from the toxic effects of certain foods. This view has important clinical implications. Mckerracher et al. (2015) have argued that recognizing pregnancy as an adaptation rather than a pathology requires a change in language within the clinical literature: Rather than describing NVP as a “syndrome,” which suggests that it is pathological, they suggest using a more neutral vocabulary such as describing NVP as “the expression of one or more behavioral and physiological traits.” In addition, Sherman and Flaxman (2002) propose that viewing pregnancy sickness as adaptive may provide some comfort to women developing NVP and help health carers to develop new ways of reducing these symptoms (e.g., the removal of potentially triggering stimuli from the patient’s environment during the first trimester).

► [Gestational Diabetes and Maternal-Fetal Conflict](#)

Prehistoric Human Art

Arthur C. Durband
Kansas State University, Manhattan, KS, USA

Synonyms

[Cave art](#); [Cave painting](#); [Petroglyphs](#)

Definition

Ancient products of human creative expression.

Introduction

Evidence for artistic expression is a relatively recent phenomenon in the evolution of humans. Prior to the Late Paleolithic, most human activity

was centered on subsistence with precious little time left for other pursuits. The oldest artwork currently recognized is a series of petroglyphs at the site of Bhimbetka, India, that have been dated to at least 290,000 years ago and could be somewhat older.

Prehistoric Human Art

Prehistoric art is generally placed into one of three categories: petroglyphs (carving or scratching into a stone surface), parietal art (cave paintings), or mobiliary art (small, portable items like figurines or other sculpture). Many of these forms can be quite difficult to obtain dates for, so the temporal context for many works of prehistoric art is highly subject to revision as new dating techniques are developed and existing techniques are improved.

Petroglyphs are made by pecking or scratching the surface of a stone face, often to reveal layers of lighter unweathered stone underneath. They have been found all over the world, with the most significant installations in parts of Africa, Scandinavia, Europe, and Australia.

Parietal art refers to any artwork made in caves, including cave paintings and engravings made on the walls, floors, or ceilings of caves. Such artwork may be produced using charcoal or a variety of pigments such as ochre or manganese. A number of dating techniques can be used to date materials involved in the production of such paintings to obtain an approximate age, and in some instances foreign substances like mineral deposits overlaying the artwork may also be used to estimate a minimum age of the artwork. Parietal artwork has also been found around the world, with noteworthy examples in Africa, North America, Australia, and Europe.

Mobiliary art is any small-scale artwork that is movable. This can include carvings, sculpture, or engraved tools. A number of different materials were used to create these works, including stone, bone, ivory, and ceramics. Perhaps the most famous mobiliary art is the Venus figurines that first appeared during the Late Paleolithic of Europe. These small statuettes depict rather exaggerated versions of the female body, with large

pendulous breasts and broad hips. Other forms of mobiliary art are seen in ornate bone tools like spearthrower handles and decorated harpoon heads.

Due to the relatively recent appearance of artwork in the archaeological record, it has often been cited as evidence for the appearance of the advanced intellect of modern *Homo sapiens*. However, there is a small but growing body of evidence that suggests that Neandertals were also capable of producing artwork. Eagle talons discovered among Neandertal remains in Krapina, Croatia, show signs of having been worn as jewelry (Radović et al. 2015). At Bruniquel Cave in France there is evidence that Neandertals created rings with broken stalagmites over 175,000 years ago, considerably older than the first appearance of modern humans in Europe (Jaubert et al. 2016). La Ferrassie, France, site of a series of seven Neandertal burials, also contains petroglyphs in the form of cupules in the cave walls and on a stone slab placed over the burial of a child. These discoveries, among others, highlight the behavioral complexity of Neandertals and the inherent difficulty in interpreting the significance of prehistoric artwork.

Conclusion

Prehistoric human art provides insights into the development of humans' capacity for symbolism, complex thought, and creativity. These types of expression are often considered hallmarks of humanity that separate *Homo sapiens* from our ancestors. Recent discoveries of artwork attributed to Neandertals may require us to either change our perception of the significance of this artwork or to alter our perceptions of the Neandertals and their relationship to *Homo sapiens*.

Prejudice

Paula M. Brochu and Katherine H. Cadwalader
Nova Southeastern University,
Fort Lauderdale, FL, USA

Synonyms

[Antipathy](#); [Attitude](#); [Bias](#); [Ingroup favoritism](#); [Outgroup derogation](#); [Preference](#)

Definition

Prejudice is an attitude, or an overall negative evaluation or devaluation, of a social group and its members. Prejudice entails affective reactions toward social groups (e.g., anger, fear, disgust, pity, guilt, envy, contempt).

Introduction

Advancing from Allport's (1954) definition of prejudice as "antipathy based upon a faulty and inflexible generalization" (p. 9), prejudice is defined as an overall unfavorable evaluation of, or attitude toward, a social group (Crandall and Eshleman 2003; Esses et al. 1993; see also Dovidio et al. 2005). Prejudice may include elements of outgroup derogation and ingroup favoritism, and can be understood in terms of direct antipathy toward outgroups as well as relative preference for ingroups (Brewer 1999). Thus, prejudice may not entail a strictly negative attitude toward a social group, but encompasses a

relative devaluation of one social group compared to another. In addition to prejudice as a general attitude or evaluation, prejudice is an affective state that entails emotional reactions toward social groups (Esses et al. 1993). In the United States, for example, African-Americans tend to elicit fear, whereas Native Americans tend to elicit pity, gay men tend to elicit disgust, and activist feminists tend to elicit anger (Cottrell and Neuberg 2005).

Overview

Prejudice is conceptually distinct from stereotypes (i.e., cognitive beliefs about the attributes and traits of a social group and its members) and discrimination (i.e., any negative, unfair, or unequal behavior or treatment accorded to others based on group membership), although these concepts are interrelated (Esses et al. 1993). Conceptualization of prejudice as an attitude necessitates consideration of prejudice in terms of propositional processes (e.g., explicit attitudes) and associative processes (e.g., implicit attitudes; Gawronski and Bodenhausen 2006). Considering the more automatic and spontaneous aspects of prejudice along with its more controlled aspects allows for a better understanding of the various ways in which prejudice is expressed, ranging from rather overt and blatant expressions (e.g., old-fashioned prejudice; McConahay 1986) to more subtle instantiations (e.g., modern prejudice and aversive prejudice; Dovidio and Gaertner 2004; McConahay 1986). Any conceptualization of prejudice would be remiss without acknowledging the functions that prejudice serves, which include the object-appraisal function, social expressive function, and value expressive function (Herek and McLemore 2013). Considering prejudice as an affective state allows for more nuanced understanding of how group stereotypes (Cuddy et al. 2007) and perceived group threats (Cottrell and Neuberg 2005; see also Stephan et al. 2016) differentially elicit intergroup emotions in predictable ways. Each of these areas forms a foundational basis in understanding prejudice and are elucidated below.

Implicit Versus Explicit Prejudice

Prejudicial attitudes may be implicit or explicit. Whereas implicit attitudes are automatic affective reactions toward a social group, explicit attitudes are controlled evaluative judgments (Gawronski and Bodenhausen 2006). Implicit attitudes are activated automatically upon encountering a social group, regardless of whether a person considers the associative evaluation to be accurate, and regardless of whether a person even intends to evaluate a group. Anecdotally, implicit attitudes are analogous to a “gut reaction” that may be experienced when approaching a shadowy stranger on a dark street. By contrast, explicit attitudes are evaluative judgments that a person endorses and believes to be true. Explicit attitudes are dependent on the assignment of truth values, intentional, and require cognitive resources to make syllogistic inferences. In other words, explicit attitudes are endorsed statements of people’s social group preferences. For example, prejudicial sentiment likely bases the statement “No fat chicks” recently seen on a bumper sticker.

People typically use their automatic affective reactions as the basis for their evaluative judgments (Gawronski and Bodenhausen 2006). However, prejudice is one domain in which implicit and explicit attitudes do not routinely match. For example, a person may have an automatic negative reaction toward African-Americans even though they may not personally endorse the negative associative evaluation (Devine 1989).

Forms of Prejudice Expression

Historically, prejudice has been studied in the form of direct, blatant expression of negativity toward social groups, which can be described as old-fashioned prejudice. Old-fashioned prejudice may be best conceptualized in terms of non-egalitarian beliefs, as it entails blatant antipathy toward social groups and the belief that some social groups are inferior to others (McConahay 1986). This form of prejudice is labeled old-fashioned because it is no longer acceptable in

most social circles. In fact, public opinion polls in North America have shown a steady decline in the negative evaluations of racial minority groups after World War II, mirrored by a steady increase in the endorsement of racial integration and equal treatment (Bobo 2001). Nevertheless, people vary in their endorsement of old-fashioned prejudicial attitudes. It depends on the social group in question as well. For example, some prejudices are relatively socially acceptable (e.g., negative attitudes toward illegal immigrants, ex-convicts, fat people) whereas others are socially unacceptable (e.g., negative attitudes toward blind people, Black Americans, Jews; Crandall et al. 2002).

Over the last few decades, researchers have proposed and refined theories of more subtle forms of prejudice, such as modern and aversive prejudice, due to observations of changing societal and personal norms regarding the overt expression of prejudice. Modern prejudice is exemplified in the case where people minimize diversity and group difference, deny the existence of discrimination, and thus do not support public policies aimed at reducing discrimination, such as affirmative action (McConahay 1986). From this perspective, prejudicial attitudes are expressed as concern over how group equality should be implemented. In this way, underlying negative attitudes toward particular social groups are justified on nonprejudicial grounds, thus allowing for the maintenance of an egalitarian and nonprejudiced self-image. For example, you may have heard someone make a statement like, “If I was Black, then I would have gotten that job.” This exemplifies modern prejudice as it denies discrimination, minimizes diversity issues, and communicates dissatisfaction with policies aimed to reduce discrimination.

Aversive prejudice is another subtle, often unintentional form of prejudice in which people hold strong egalitarian values, and, at the same time, harbor negative feelings and beliefs toward minority groups based on socialization and categorization processes (Dovidio and Gaertner 2004). From this perspective, people are socialized to be egalitarian and nonprejudiced, while also internalizing negative feelings and beliefs about stigmatized social groups. Aversive

prejudice focuses on the conflict between people’s denial of personal prejudice (i.e., explicit attitudes) and their underlying negative attitudes toward particular social groups (i.e., implicit attitudes). Notably, the theory of aversive prejudice argues that prejudice will only be expressed when people can justify it on nonprejudicial grounds, allowing people to maintain an egalitarian image. Otherwise, people may bend over backwards to demonstrate how nonprejudiced and accepting they are, especially if prejudice-related issues are salient.

The integrative prejudice framework (Brochu et al. 2008; Gawronski et al. 2012) specifies the conditions under which negative affective reactions toward social groups translates into negative evaluative judgments. It identifies egalitarian nonprejudicial goals (i.e., the extent to which one believes that negative evaluations of social groups are wrong) and perceptions of discrimination (i.e., the extent to which one believes that a specific social group is a target of discrimination) as central components that distinguish old-fashioned, modern, and aversive prejudice. Specifically, the correspondence between implicit and explicit prejudice is determined by the interplay between egalitarian nonprejudicial goals and perceptions of discrimination according to cognitive consistency principles. Research evidence indicates that explicit attitudes about a social group reflect implicit attitudes when nonprejudicial goals are weak and at the same time perceived discrimination is high, reflecting central components of old-fashioned prejudice (i.e., believing that discrimination of some groups is pervasive and that this discrimination is acceptable, even preferred). Further, explicit attitudes about a social group reflect implicit attitudes when nonprejudicial goals are strong and perceived discrimination is low, reflecting central components of modern prejudice (i.e., believing that discrimination is wrong but that discrimination is a thing of the past). Moreover, explicit attitudes about a social group do not reflect (or may even negatively reflect) implicit attitudes when nonprejudicial goals are strong and perceived discrimination is high, reflecting central components of aversive prejudice (i.e., believing that discrimination is

wrong but at the same time harboring negative underlying views about particular social groups).

More generally, the expression of prejudice can be understood from the perspective of the justification-suppression model of prejudice (Crandall and Eshleman 2003). In this model, genuine prejudice is distinct from expressed and experienced prejudice. Genuine prejudice is an authentically negative reaction toward social groups that develops from several social, cultural, cognitive, and developmental factors, including family influences, direct cultural learning, social categorization, group identity, intergroup contact, and intergroup conflict. Genuine prejudice undergoes a range of suppression and justification factors that shape how prejudice is expressed and experienced to the self and others. Suppression factors reduce the expression or awareness of prejudice and include social norms, empathy, personal standards, egalitarian beliefs, and values. Justification factors release the expression of prejudice without guilt or shame and include belief in a just world, Protestant work ethic, social dominance ideology, victim blaming, attributional scapegoating, situational ambiguity, shifting standards, and perceived threat, to name just a few.

Functions of Prejudice

A variety of motivations underlie prejudice, as attitudes can serve different functions. The basic assumption is that people hold and express attitudes because they fulfill psychological functions (Herek and McLemore 2013; see also Maio and Olson 2000). One function of attitudes, including prejudice, is object appraisal. Attitudes allow people to categorize objects into groups and then evaluate them accordingly. Applied to prejudice, attitudes allow people to recognize different social groups and label them as good or bad; having this knowledge assists people in making behavioral decisions, such as whether to approach or avoid a person who belongs to a particular social group. Importantly, object appraisal is the outcome of a normal cognitive process in which people automatically

categorize others into social groups to organize the world in a meaningful and consistent fashion. Social categorization into groups, like all categorization processes, highlights the similarities within groups and the differences between them (Brewer 1999). Intergroup conflict depends on the categorization of social groups into us versus them, as social categorization predisposes people to prefer ingroup members to outgroup members. This is remarkably easy to elicit: People prefer ingroup members even when they are assigned to groups temporarily according to arbitrary dimensions (e.g., minimal groups; Tajfel et al. 1971).

Another function of attitudes is that of social expression (Herek and McLemore 2013; Maio and Olson 2000). Attitudes allow people to express their sense of belonging to particular social groups, and assists people in gaining acceptance, approval, or love from others they consider important, such as family, friends, coworkers, and neighbors. In this way, the expression of prejudice is one way that may allow people to fulfill their affiliative needs. For example, Herek (1987) found that people's attitudes toward gay men and lesbians were at least partially based on their "perceptions of how the people I care about have responded to gay people as a group" and "learning how gay people are viewed by the people whose opinions I most respect" (p. 296). The self is defined largely in terms of group memberships, and as such, groups are an important source of identity for people (Tajfel and Turner 1986; Turner et al. 1987).

Attitudes also serve a value-expressive function, allowing attitudes to affirm people's belief in and adherence to important values that are closely related to their self-concept (Herek and McLemore 2013; Maio and Olson 2000). In this way, the expression of prejudice is one way that may allow people to display aspects of their identity that are based on moral, ethical, or political principles. For example, Herek (1987) found that people's attitudes toward gay men and lesbians were at least partially based on their "concern that we safeguard the civil liberties of all people in our society" and "moral beliefs about how things should be" (p. 296).

Prejudice as Affect

Simply conceptualizing prejudice as an overall negative attitude toward a social group and its members may obfuscate the nuanced complexity that different social groups elicit qualitatively different affective reactions. For example, people may report similar levels of prejudice toward two groups on an attitudinal measure, but may experience different emotional reactions to the two groups (e.g., fear versus anger; Cottrell and Neuberg 2005). This consideration is particularly important as emotions have motivational force; they serve as a spur to action (Crandall and Eshleman 2003; Cuddy et al. 2007).

According to the BIAS map (Cuddy et al. 2007), judgments of warmth and competence underlie social perceptions and drive our emotional and behavioral reactions to others. Upon encountering a person or a social group, people first seek to anticipate their intentions – do they intend to help me or harm me and my group? – and this leads to categorization based on warmth (e.g., trustworthy, kind, friendly). Then, people seek to know others' capability to pursue their intentions – are they able to help me or harm me and my group? – leading to categorization based on competence (e.g., creative, confident, intelligent). If a social group is perceived as lacking warmth, this tends to elicit dislike, whereas if a social group is perceived as lacking competence, this tends to elicit disrespect. Furthermore, judgments of social groups based on warmth and competence lead to predictable emotional reactions. Groups perceived as low on warmth and low on competence, such as the homeless and the poor, tend to elicit contempt. By contrast, groups perceived as low on warmth and high on competence, such as Asian Americans and the rich, tend to elicit envy. Furthermore, groups perceived as high on warmth and low on competence, such as the elderly and housewives, tend to elicit pity. And, groups perceived as high on warmth and high on competence, such as one's ingroups, tend to elicit admiration.

In Cottrell and Neuberg's (2005) sociofunctional approach to prejudice, specific feelings

that people have toward members of other groups are argued to depend on the specific tangible threats that these groups are perceived to pose. Qualitatively different group-based threats evoke qualitatively different affective reactions. For example, some groups are perceived to be threatening because they are viewed as a risk to physical safety, arousing fear. Other groups are perceived to be threatening because they are perceived as obstructing a desired outcome, such as threatening group economic resources or personal freedoms and rights of ingroup members, arousing anger. Some groups are perceived to be threatening because they are viewed as physical or moral contaminants, either through threat to group health via contagion or threat to group values, arousing disgust. Other groups are perceived to be threatening because they possess resources or opportunities that one lacks, arousing envy. Some groups are perceived to be threatening because they are disadvantaged for reasons beyond their control, eliciting distress and feelings of pity. Other groups are perceived to be threatening because they threaten the perception of the morality of one's ingroup, eliciting distress and feelings of guilt. It is clear that social groups pose multiple threats and elicit a variety of emotions.

Prejudice from an Evolutionary Perspective

Evolutionary processes can inform psychological research on prejudice (Schaller et al. 2010). From an evolutionary perspective, prejudice can serve meaningful purposes that benefit group outcomes. For instance, Neuberg et al. (2000) argue that prejudice is rooted in an inherent need to live in effective groups that promote survival. Human beings are social animals, and are greatly committed to group living. Interdependent and cooperative groups likely evolved to maximize survival; people are able to more easily secure fundamental resources like food, water, shelter, and mating partners that support child rearing and self-protection initiatives by living and working with others. Group living has its risks, however, and so

humans possess cognitive adaptations that alert them to others who may be likely to physically harm fellow group members, spread contagious disease, or free ride on the efforts of the group (Kurzban and Leary 2001; Schaller and Neuberg 2012). Thus, groups who are perceived to threaten the survival of one's ingroup will be the target of prejudice. Furthermore, the preference of some people to express domination over others may be understood from the adaptive utility of status hierarchies within social groups (Pratto et al. 1993). The process of prejudice can be considered a byproduct of evolutionary processes, in which prejudice functions to minimize threat by derogating others and maximize survival by aligning with strong ingroup members.

Even though the roots of prejudice may lie in the evolutionary past of humans, this does not imply biological determinism (Neuberg et al. 2000). Just because certain prejudices were adapted for the social and physical environments of the evolutionary past does not imply that they are adaptive today. Furthermore, even if some prejudices are adaptive, evolutionarily speaking, this does not mean that they are acceptable or justifiable.

Conclusion

In a time when the US government seeks to ban visitors from Muslim-majority countries and all refugees, and the nation is reeling from violence targeting stigmatized group members, including LGBT-identified people, Jews, and Blacks, prejudice remains an important social issue (Society for the Psychological Study of Social Issues 2017). Understanding prejudice, including its associative and propositional processes, forms of expression, functions, and affective aspects, allows researchers to better develop effective prejudice-reduction interventions. As Neuberg and Schaller (2016) point out, humans are *evolved* social animals, and research that considers prejudice from an evolutionary perspective has the potential to inform understanding of the nature of prejudice.

Prejudice as an Expression of Tribalism

Onurcan Yilmaz

Kadir Has University, Istanbul, Turkey

Synonyms

Racism and prejudice; Tribalism; Tribalism in moral tribes

Definition

People show a set of tribalistic tendencies such as ingroup favoritism and outgroup discrimination since they were adaptive in the past environmental conditions. In other words, groups that showed stronger ingroup favoritism and outgroup discrimination were more likely to survive in the past selective pressures. Therefore, prejudice can

be seen as a reflection of our evolved tribalist psychology.

Introduction

The finding that people cooperate more with members of their own group and thereby show tribal tendencies has been established in many different areas of research (Balliet et al. 2018; Fowler and Kam 2007; Yamagishi and Mifune 2016). For example, Ben-Ner et al. (2009) showed that when people share an identity (religious, political, etc.), they tend to make clear distinctions between ingroups and outgroups in their intended and actual social behavior. Other research shows that newborns show preferential behavior towards their own race and discriminate against those who do not speak their own language (Bar-Haim et al. 2006). Even in the minimal group paradigm, where groups are generated randomly, people show ingroup favoritism (Tajfel and Turner 1986). This tendency is observed in other primates as well. For example, capuchin monkeys can automatically distinguish the faces of ingroup and outgroup members (Mahajan et al. 2011). In fact, De Waal et al. (2008) showed that capuchin monkeys behaved prosocially toward their ingroup members but not toward the outgroup. In short, discrimination and prejudiced attitudes toward outgroups arise as a result of ingroup favoritism among both humans and our close relatives.

Prejudice is defined as preconceived opinions or attitudes, usually based not on a rational evaluation of evidence that a person has about another party (Allport 1954). Instead, prejudice is usually based on automatic judgments (Bargh 1999) and manifests itself implicitly at the perceptual and physiological level (Payne 2006). Likewise, as the human species evolved in intense intergroup conflicts involving coalition building (Geary 2005), cooperation was often only directed toward own group members. In general, it is thought that selective environmental pressures caused humans to acquire tribal characteristics including prejudice, since groups that showed stronger ingroup favoritism were more successful than others.

These coalitional conflicts manifest themselves in today's world as well. However, there is an ongoing debate as to whether all political groups have these tribal characteristics equally. In a meta-analysis by Jost et al. (2003), asymmetries between the liberals and the conservatives were found on many areas related to tribalism (e.g., ingroup favoritism, closed-mindedness, prejudice, etc.). For example, conservatives are more biased toward outgroups than liberals. However, these studies were later criticized on methodological grounds (i.e., Brandt et al. 2014). The most important of these criticisms is that past studies chose to study minority groups that the liberals favor (gays, atheists, etc.) as the target of prejudice. Interestingly, liberals reported more prejudiced attitudes than conservatives when minority groups favored by conservatives were selected, such as religious people (Brandt and Van Tongeren 2017; Brandt 2017). In other words, both ideological groups reported prejudice against groups that are not similar in value to themselves. This suggests that people tend to cooperate with ingroups – independent of political ideology – and support the argument that prejudice is a reflection of evolved tribalist intuitions.

In an attempt to explain the psychological differences found between liberals and conservatives, Haidt (2012) states that each political group originally has tribal characteristics, but that liberals spend cognitive effort to repress these tribal characteristics (such loyalty, authority, and sanctity). There is some evidence suggesting that liberals resemble conservatives when their cognitive resources are depleted through cognitive load or existential threat (e.g., Nail et al. 2009). Haidt's theoretical approach, therefore, supports the argument that everyone has a set of tribalistic tendencies and that favoring the ingroups and derogating the outgroups stem from our evolved psychology. Hence, prejudice reflects human nature, evolved due to function in past environmental conditions. One way to avoid such cognitive biases in general (Kahneman 2011) and prejudiced attitudes in particular (Yilmaz et al. 2016) is to promote the processes of effortful and analytical thinking.

Introduction

Sexuality colors the whole life of an individual, since the early childhood; the sexuality develops throughout individual life, leading to certain beliefs and attitudes about sexual relationships. Going toward adolescence, sexual relationships provoke interest among one and all. Sexual relationships can be comprehended as constant choices that one makes in their lives to engage in sexual activities. This is although a biological instinctual process in the beginning, but due to the complexity of human society, sexual permissiveness shows a great degree of variation throughout the world (Friedman 1992).

Marriage is a norm in all of the civilized human society which acknowledges the union of two human beings and grants them the permission to reproduce in a culturally accepted manner. In major cultures of the world, men and women are considered not to engage in sexual relationships before marriage which has been religiously governed majorly as chastity and strength of character (Zuo et al. 2012). Historically, men and women who engaged in premarital sexual acts were considered impure and unchaste which degraded their social status and also made them lose their honor (Ghaffari et al. 2016). These values color the sociocultural aspects of Christianity, Hinduism, Islamic, and Jewish societies majorly covering most of the human population (Gaje 1996; Reiss 1964a; Spercher and Hatfield 1996).

During the rapid urbanization and development of the western world with the insights of Sigmund Freud and liberalization of the society, premarital sexual permissiveness became an area of study, and during the 1960s, researches started happening in the United States of America followed by the rest of the world. It still remains an interesting area for research and study (Zuo et al. 2012).

Concept of Sexual Permissiveness

There are certain terms associated with sexual permissiveness:

- *Permissive society*: this is a type of society which is considered to be open to the ideas of sexual freedom. This type of society has existed in Europe, North America, and Australia. Here, people are allowed to engage in sexual activities before marriage (“Permissive society” 2018).
- *Liberalism*: liberal comes from the word liberty, which allows a person to think and hold varied and different philosophies. This liberty in the late 1960s in America and Europe not only remained as philosophical but also became broadened to accommodate with sexual freedom, which allowed the members of the society to enjoy the choice of choosing their own partners and engaging in sexual activities. But then this was considered as a bad label, as it meant high level of sexual promiscuity among the people of their society.
- *Secularism and permissiveness*: these two words are often related as permissiveness which was found to be closely related to secularism. As the secularism became more and more prominent in the western countries, their permissiveness increased.
- *Premarital sexual permissiveness*: literally means the mind-set of accepting sexual behavior before marriage.

The people of the Victorian era and the strong religious sentiments of Christianity started becoming more secular with the rise of Marxism and communism, leading to a more secular and irreligious societies during the 1960s, where mutual love preceded the religious rigor, and along with liberal philosophies, the sexual liberation also took place, and no longer the sexuality was something to be frowned upon, rather became acceptable in its all-pervading variants including the LGBTQ. Homosexuality was no longer considered a criminal offense. This type of change wave later rippled throughout the world and still affecting the global society (Reiss 1964a).

Factors Affecting Premarital Sexual Permissiveness

Gender: Gender has always played an important part in sexual preferences and activities as in all the cultures of the world, there are certain gender roles prevalent among the male and female gender. This in turn affects their sexuality significantly (Cheng et al. 2012). Sexual permissiveness among males are found to be more liberal, and their willingness to engage in sexual behaviors was much more prevalent and acceptable (Cheng et al. 2012; Zuo et al. 2012). According to a study in Eastern Asia where the “Confucian” beliefs prevail, it was found that male to female premarital sexual permissiveness was significantly different as the stigma related to sexual promiscuity was prominent and women were expected to be faithful to their husbands

completely during life and even after death, whereas among the western countries in the permissive societies, women and men both had a more acceptable outlook toward premarital sexual relationships (Debnam et al. 2017).

Age

Age has been a very important factor in deciding sexual permissiveness. In a study of African American population, it was found that adolescent girls would prefer to be in relationships with older boys belonging to racially, ethnically, and socio-demographically matched households (Carver et al. 2003). As the onset of puberty has reduced, sexual activities have become a greater interest among the younger age groups. Even though the premarital sexual relationships are majorly found among the age group of high-school students and above, a study from China and Vietnam showed that more number of adolescents are being exposed to sexual behaviors due to access of the Internet and pornography, so the average age of sexual involvement is continuously lowering for both boys and girls showing increase in premarital sexual permissiveness among younger age groups throughout the world (Zuo et al. 2012).

Religious Beliefs

Religious beliefs have a very important impact on the sexual permissiveness among the unmarried people. The regions of East Asia show that females most prominently abstained from premarital sexual relations as they would break religious taboos, which might affect their social status and marriage-related prospects (Zuo et al. 2012). A study from Iran (Ghaffari et al. 2016) stated that premarital sexual activities occurred rarely as it was considered to be un-Islamic and sin, which also provides evidence for the high impact of the religious sentiments on the premarital sexual behaviors. Although the European societies are considered permissive societies, it was found that their closeness with the religion often had restrictive mind-sets compared to the liberal ones (Spercher and Hatfield 1996).

Media: According to a study (Lou et al. 2012), media plays a very important part in development of the sexual attitudes. It was also found that the

concepts about sexuality were mainly influenced by the media content they were accessing which was instrumental in developing the concept of sexual permissiveness before marriage (L'Engle et al. 2006). A study among the black and white American adolescents from middle school was conducted regarding the sexual content from the Internet, books,, magazine, television, and mass media. The results showed that the sexual content in those platforms influenced their behavior and perception intention and variances in sexual behaviors. The rates of premarital sexual behaviors have been increasing continuously in the East (Lou et al. 2012). The role of media is associated with it. These videos and ease of access to pornography and sexual content through various methods have exposed the adolescents with premarital sexual behaviors, and study also found that sexual experiences have become more and more common at younger age group with the ease of access to various mass media and the Internet.

Social Belief Systems

Social belief system has always played an important role in shaping the sexuality, regarding the acceptable and unacceptable behaviors. A study among the unmarried college students of American, Russian, and Japanese nationalities found that American people were more acceptable in terms of premarital sexual relationships compared to their Russian and Japanese counterparts (Spercher and Hatfield 1996). A study from Hanoi, Taipei, and Shanghai found that the impact of confusion cultural values was prominent in Hanoi, but among the people of Shanghai, social beliefs were found to be inversely proportional with premarital sexual permissiveness and had more chances of being exposed to such activities. A study from the Middle East suggests that the prominent Islamic belief systems influence the sexual permissiveness and majorly the unmarried men and women were less likely to engage in premarital sexual activities (Ghaffari et al. 2016). A study from sub-Saharan Africa shows that there is a great impact of social beliefs in making early reproductive decisions and they have a great impact on the overall society (Gaje 1996).

Knowledge About Health Risks

The knowledge about the health risks has always impacted the premarital sexual behavior. A study from India (Naik et al. 2005) found that the Tribal population of India was migrating toward the cities and due to their permissive cultures posed a greater risk of HIV and AIDS compared to the other city counterparts. A study from the developing countries states that the awareness about the sexually transmitted diseases was directly related to sexual permissiveness of people (Friedman 1992). The similar pattern of association was also found among the college students of developed countries as well (Friedman 1992; Spercher and Hatfield 1996). Among the Far Eastern countries, the knowledge about the sexual and reproductive diseases remained an associated factor governing the premarital sexual permissive behaviors among both genders (Zuo et al. 2012).

Perceptions of Gender Role Expectations and Traditional Norms

The variations among sexuality are very prominent among the genders and so are their roles. Similarly there is a great variation among the premarital sexual permissiveness among both the genders concerned. Studies throughout the world show that males are comparatively more permissive of sexual behaviors comparatively to their women counterparts (Friedman 1992; Hipwell et al. 2013). The Asian cultures are comparatively less permissive compared to the western cultures; here the variations are more prominent as the role expectations here are mainly passive and recipient of sexual behaviors and are least likely to initiate as per the cultural norms expected from them. Different behaviors from their side would end them being labeled in a derogatory manner (Cheng et al. 2012). Similar findings were also from another Asian study (Zuo et al. 2012).

The other important factors that influence the premarital sexual permissiveness are availability of gender-sensitive sex education (Zuo et al. 2012). This gives the adolescents the right kind of knowledge about the sexual behaviors and the safe sexual practices which will not physically or mentally harm them. The access to right socially sensitive sexual education can have a protective

effect on the premarital sexual permissiveness and behavior (Cheng et al. 2012).

Stigma: Most of the cultures throughout the world have observed that women who had openly stated their sexual desires were often stigmatized, and in less permissive societies, chastity has been considered as an important virtue among women; thus this has been a very important psychological determinant throughout the world among women to refrain from premarital sexual relationships (Debnam et al. 2017; Ghaffari et al. 2016; Zuo et al. 2012).

Area of residence: It has been observed throughout the world that urban and rural cultures have differences in their social structures and also influence the patterns of perception premarital sexual behaviors. There has been a significant difference among the people residing in urban and rural areas (Cheng et al. 2012; L'Engle et al. 2006; Naik et al. 2005).

Scales for Measurement of Premarital Sexual Permissiveness

Guttman had developed scales for measuring premarital sexual permissiveness at Iowa University. These scales were found to be very effective in measuring permissiveness and differentiating high permissive and low permissive groups and have many subsections which can be used for studying separate topics of research (Reiss 1964b). These scales are validated and studied in further literature after the 1960s. The scale is divided into sections: standards for men containing 12 items and standards for women (12 items section) and a feedback section. This scale has been widely accepted and adapted for.

Premarital Sexual Permissiveness Among Various Ethnicities

The studies of the 1960s found that the sexual permissiveness among the blacks and the whites varied considerably (Friedman 1992). The main factors found in low permissive groups of whites were church attendance and belief in romantic

love, and the permissiveness increased more with the number of love relationships, whereas among blacks these associations were not significant (Debnam et al. 2017; Zuo et al. 2012). There have been gender differences among the adolescents and young adults regarding premarital sexual permissiveness all over the world. A study from Asia reports that there are various factors influencing the behavior, and the main associated factors presented in the studies are the “Confucian Beliefs” (Cheng et al. 2012; Zuo et al. 2012). The Middle Eastern communities have also shown to have more restrictions among women compared to men as sexual relationships before marriage are not permitted among the Islamic culture although there were gender differences, which were similar to other Asian region communities (Ghaffari et al. 2016).

Conclusion

Sexuality plays a very important part in human life and is a necessary aspect of life; it's a process where we preserve the progeny that exists in the world.

A systematic review of sexual practices among the adolescents (Friedman 1992) states that with sexuality is an inevitable part of human life and exists in our instincts, and it plays an important part in human growth, development, and maturity. It is already known that adolescence is a period of great storms in one's life; it also marks the beginning of sexual maturity. New dimensions are created during this time of life sexually; it is marked by intense feelings and emotional turmoil. Complexity of relationship increases, which leads to drastic outcomes and consequences in terms of sexual behavior. These changes affect not only the individual but also their societies at large (Carver et al. 2003). The contemporary times the lives of adolescents are confronted with a great deal of challenges which has changed very drastically in the previous few decades. This change brings about various patterns of sexual behavior. These changes are not only in the external world but also impacting their biology the changing world has

brought about changes in their biology as well like earlier puberty, delayed marriage, increased focus on individuality and less control by family and more autonomy these can be attributed as some significant factors. Intense exposure to sexual stimuli via the mass media and the Internet gives access to everything on fingertips (L'Engle et al. 2006). Increasing globalization and diminishing cultural boundaries have led to increased premarital adolescent sexual activity. This has only added to traditional existing problems of early marriage. Newer problems of like early pregnancy, childbirth, and induced abortion outside of marriage are sexually transmitted diseases and human immunodeficiency syndrome infection leading to acquired immunodeficiency syndrome (Naik et al. 2005). Various studies have strongly recommended age-appropriate sexual education in diminishing the high-risk behaviors pertaining to premarital sexual permissiveness, such as increased trust, and responsible sexual behavior among both the sexes will minimize the impacts of premarital sexual behaviors as it cannot be completely prevented, as well as can be handled in a way which promotes minimal harm and maximal maturity among the people.

[Fetal programming](#)

Definition

The period of development extending from conception to delivery. The influence of this environment on the developing fetus can lead to permanent alterations in psychological and physiological outcomes.

Introduction

The flow of resources between parent and offspring is unidirectional. Across species, parents are the arbiter of resources – mothers determine the amount of resources (i.e., calories) allocated to offspring from the moment of conception.

Conventionally, psychological research has focused on environmental influences during infancy and early childhood as critical determinants of a child's later mental and physical health outcomes. However, converging evidence from a variety of disciplines – e.g., biology, anthropology, medicine, and epidemiology – has found that environmental input received by a developing fetus during the period extending from conception to infancy (i.e., the prenatal environment) can have permanent imprints on an organism's physiological and psychological development. The impact of this recent research interest in “fetal programming” is widespread and has implications for numerous fields including evolutionary psychology.

Within developmental biology, research on the “developmental origins of health and disease” (DOHaD) has recently benefitted from a more explicit focus on evolutionary principles (Gluckman et al. 2007). The core of the DOHaD hypothesis is simple: conditions early in development, including in utero, can have an enduring impact on one's developmental outcomes and these early influences may affect susceptibility to illnesses and diseases with onsets that occur much later in life. Many of these changes are associated with alterations in gene expression (epigenetics) affecting the hypothalamic-pituitary-adrenal (HPA) axis – a system responsible for the transduction of environmental information (e.g., nutritional status, psychosocial stressors) into signals that an organism can use to direct developmental timing and tempo. In animal studies, epigenetic changes in the HPA axis activity are associated with permanent changes in adult behavior and stress responsivity (see Turecki and Meaney 2016 for review). Using the guiding principles of evolutionary theory, researchers have started to look at such early “calibration” as *adaptive* responses to environmental input (as opposed to strictly pathological).

Background

Contemporary research on the sizeable impact of the prenatal environment on adult outcomes has

its origins in the work of Barker and colleagues who reported that rates of heart disease in the United Kingdom were more closely linked to environmental conditions when patients were born rather than to their current environment (Barker et al. 1989). It was clear that maternal conditions in the prenatal period had a lasting impact on the emergence of later developmental outcomes. This early work focused on size at birth as a proxy for prenatal conditions. A number of studies link small size at birth (a consequence of constrained prenatal energy availability) with adverse effects on the risk of chronic diseases later in life. The cluster of chronic diseases associated with metabolic alterations and modifications of glucose metabolism are particularly implicated.

Despite the clear detriment of increasing one's propensity for chronic disease in adulthood, these metabolic changes might also have adaptive value to the developing fetus in the short term. For example, a deprived prenatal environment (i.e., restricted calories) might help calibrate a fetus to permanently develop a "thrifty phenotype" by being small and insulin resistant through the early postnatal period and into adulthood (Turecki and Meaney 2016). In turn, as an adult, the individual would be well suited to an environment in which nutrient supplies were limited as their metabolic machinery "fits" with that of a resource-scarce environment. However, this individual would be more likely to become unhealthy in a nutritionally *rich* environment – a scenario in which the postnatal environment is at a mismatch with the environment predicted from the prenatal period.

Prenatal Environment as a Forecast

This adaptive calibration of one's phenotype in response to environmental signals received early in development (i.e., in utero) is a hallmark of the concept of developmental plasticity. From an evolutionary perspective, costly alterations in early development can be viewed as normal, adaptive responses to challenging prenatal environments. Postnatal pathology arises when the cost-benefit

trade-offs with other components of fitness calibrate developmental trajectories that increase short-term survival at the cost of increased health complications and shortened lifespan in the long term. These costs may include low birth weight, preterm birth, heightened stress reactivity, early reproductive development, and early mortality. However, if paying these costs would have led (on average and across ancestral development) to an increased probability of reproducing in the harsh or unpredictable environments that require them, the deleterious impact on longevity would have been a small price to pay from the perspective of natural selection (Harpending et al. 1990).

While in utero, the fetus "senses" its future environment via signals from its prenatal environment, and development proceeds as an integrated response to those signals. Gestation can be thought of as a 9-month assay of environmental conditions. This period allows the developing organism to make predictive adaptive responses (PAR) that can improve the fit between its own phenotype and the anticipated levels of challenge and threat in the postnatal environment (Gluckman et al. 2007). The mechanisms of fetal programming can only be adaptive, however, if in utero conditions are indeed predictive (more often than not) of characteristics of the postnatal environment.

There are now several lines of evidence (predominantly from non-humans) that support the idea that the prenatal environment does calibrate one's development in line with what would be expected of a PAR. For example, if signals in the developmental phase suggest limited nutrient availability, the prediction is that the organism should adjust its developmental trajectory such that the individual has a metabolic profile better suited for survival in a calorically scarce environment. Female rats subjected to undernutrition during pregnancy gave birth to offspring that developed a metabolic phenotype showing increased appetite, insulin resistance, and reduced physical activity, particularly if they are fed a high-fat diet after weaning (Vickers et al. 2003). In this example, poor prenatal nutrition led to a PAR of a poor postnatal environment. In response, a calorically thrifty phenotype developed but in

reality the postnatal environment was nutritionally rich leading to increases in chronic diseases and obesity later in life.

Toward the end of World War II, a German blockade cut off all supplies of food and fuel to Nazi-occupied regions of the Netherlands. The resulting famine devastated the region but provided a natural experiment for researchers to investigate some of the lasting effects of widespread caloric shortages – particularly the effects of famine on pregnant women and their children. Susser et al. (1998) investigated whether some of the destructive developmental effects on children of the Dutch Hunger Winter were a consequence of famine exposure in utero and not just postnatal environmental insults. They found a significant elevation of risk of psychiatric disorders such as schizophrenia among those whose mothers went through the peak of the famine during (specifically) their second trimester of pregnancy.

Forecasting Mismatch. As stated above, when an organism's PAR is correct, there will be a good match between the phenotype adopted and the environment in which the organism will later inhabit. However, when the prediction is inaccurate, there will be a mismatch between the adult environment experienced and the phenotype induced in earlier development. From the DOHaD perspective, the greater the mismatch itself, the greater the risk for adult disease. Specifically, pathologies later in life may not arise as result of poor environmental conditions in adulthood per se but are instead the result of a phenotype that did not accurately anticipate key features of the adult environment such as resource availability and the levels of harshness or unpredictability.

Because forecasting mismatches carry costs, some researchers have proposed that gestation should not be the sole assay of environmental conditions. Kuzawa's (2005) intergenerational phenotypic inertia model provided some rationale for expecting the effects of the prenatal environment to last more than one generation. Intergenerational phenotypic inertia provides the fetus with information, not only about the environment into which it will inherit but the environment into which its mother was born, and

(possibly) back a number of generations. Intergenerational phenotypic inertia may allow the fetus to cut through the "noise" of stochastic environmental conditions and, in turn, offset some of the costs of forecasting mismatches that may occur within a single generation.

Parent–offspring Conflict

The logic of Trivers' (1974) parent–offspring conflict theory states that any investment by the mother in an individual offspring that increases its chance of surviving come at a cost of the mother's ability to invest those resources in other (existing or future) offspring. A fetus' best interests are served when it can increase maternal investment in utero beyond that of what a mother may willingly provide. Conversely, a mother's best interests (in an evolutionary sense) are served when investment in an individual fetus can be decreased to levels more in line with levels that meet the minimum required for that specific fetus' survival – a strategy that would allow a mother to reallocate resources to existing offspring or future fetuses. This disagreement about the optimal levels of investment in utero is a source of great conflict.

Haig and Trivers (1995), using the logic of parent–offspring conflict theory, developed a model of maternal–fetal interaction that makes specific predictions regarding which prenatal environments might demonstrate the greatest sources of conflict. As one example, Haig observed that the genes for insulin-like growth factor 2 (IGF-2) and the IGF-2 clearance receptor (both implicated in growth regulation across species including humans) are imprinted – that is, their expression depends on which allele (that inherited paternally versus maternally) is expressed in utero. IGF-2 is expressed in the fetus from the paternal allele and the receptor is expressed from the maternal allele. The fetus drives fetal growth under paternal influences (i.e., paternal allele of the IGF-2 gene expressed). However, under maternal influences, mothers attempt to *limit* fetal growth by clearing IGF-2 from the prenatal environment.

Under conditions with low/predictable mortality rates, mother and fetus can resolve this conflict by cooperating (each can afford to give a little more). Resources available to the fetus are increased and subsequent fetal growth and postnatal health are improved. However, under harsh and/or unstable conditions, conflict can be lethal for mother and/or fetus. If the fetus survives, the reduced investment in utero may predict postnatal health complications much later in life. The application of parent–offspring conflict theory to understanding the adaptive trade-offs at work in the prenatal environment is in its nascence but will be a fruitful area of discovery.

Maternal Stress and the HPA Axis

A mother's HPA axis responds to stress with higher levels of glucocorticoid (GC) hormones (i.e., cortisol in humans). The influence of maternal stress on the prenatal environment has lasting effects on offspring physiological and psychological development, and thus, the HPA axis is a major target of inquiry in recent work. Psychosocial stress affects development of the HPA axis and does so in adaptive ways by calibrating a range of reproductive strategies mediated by HPA axis activity from infancy to adolescence and throughout adulthood (Belsky et al. 1991). Because of the involvement of the HPA axis in behavioral responses, one should expect that the prenatal environment, potentially through permanent epigenetic modification of HPA axis function in utero, influence temperament, stress responsivity, and psychiatric outcomes postnatally.

Fetal exposure to GCs are essential for development but excess levels can be harmful. Between 10 % and 20 % of maternal GCs cross the placenta to the fetus (Seckl and Meaney 2006). Maternal cortisol has an impact on fetal development of the brain and central nervous system and overexposure to GCs in utero leads to modifications in adult behavior in across species. In humans, prenatal exposure to elevated maternal cortisol is associated with behavioral and emotional disturbances

during both infancy and childhood (Seckl and Meaney 2006).

Conclusion

Evidence that prenatal conditions can be important determinants of one's adult phenotype is persuasive. In addition to the implications for research on adult-onset chronic diseases, emerging evidence supports the notion that understanding the impact of the prenatal environment on development can also offer insight into the development of specific emotional and behavioral outcomes. Animal models suggest that even moderate influence of the prenatal environment may permanently affect adult stress reactivity and can help predict some of the variation in HPA axis responsiveness. It is clear that the time scale for thinking about the influence of the "early" environment on an individual's development has been pushed back into gestation (and possibly further). Research on the prenatal environment continues to be increasingly multidisciplinary. The integration of research on the proximate mechanisms of fetal programming (e.g., endocrine and epigenetic) with the powerful theoretical lens of evolutionary biology will undoubtedly provide novel insights into how and why development unfolds as it does from conception to adulthood.

Definition

How and why the presence of children influences parental mate preferences.

Introduction

This section covers the questions, how the presence of children affects parental mate selection in a subsequent partner for a new relationship and how children are expected to actively manipulate their parent in their mate preferences for a subsequent potential stepparent.

How Parent's Age Influences Their Mate Preferences in a Subsequent Partner

The presence of children from prior relationships affects the mate selection for a subsequent relationship. As studies have shown, women's parental status is a robust predictor of lower remarriage probability. This effect is likely to be an effect of age. Individuals who remarry are about 10 years older than the mean age of people who marry for the first time. As a consequence, there are fewer eligible (i.e., unmarried) partners, resulting in declining remarriage rates. This effect is stronger for women, as men prefer even younger women as they grow older (Schwarz and Hassebrauck

2012). Thus, the pool of eligible partners for women is reduced far more than is the case for men. From the perspective of the prospective male partner, the presence of children demonstrates the fertility of the woman, but men should be reluctant to invest their resources in someone else's children. Men's parental status, however, does not reduce probability of remarriage, because their reproductive lifespan is longer than women's. Men prefer younger women as spouses and are more likely to acquire resources as they age (Ganong and Coleman 2004).

What Characteristics are Important in a Subsequent Partner?

Regarding specific mate preferences, finding a suitable stepparent who will not abuse or kill their children is especially challenging for women. The single best predictor of child abuse is living with a stepparent, even after controlling for confounds such as socioeconomic status (Daly and Wilson 1988). Children, younger than 2 years old, are much more likely to be killed when living with one stepparent and one genetic parent compared to children living with two genetic parents. Therefore, women are expected to be especially sensitive to a variety of characteristics in a potential stepfather, and they should shift their mate preferences relative to women without children (reviewed in Weekes-Shackelford et al. 2008). For example, women with children might place greater importance than women without children on finding a partner who is willing to invest in them and prospective children. Further, women with children should prefer potential stepfathers with good parenting skills to avoid the abuse of the children. Thus, emotionally stable and kind men should be especially favored by women with versus without children. Women with children, relative to women without children, for example, should lower their expectations on men's health, and especially their physical size and strength, because these cues might be perceived as a risk of abuse.

How Children Actively Manipulate Mate Preferences of their Parents for Prospective Stepparents

Finally, children are expected to actively manipulate mating decisions of their parents in prospective stepparents. From the child's perspective, a half sister or brother is only genetically related to 25 %, while the biological parent is genetically related to 50 % with her/his new child in this family. Thus, the child is expected to manipulate their parent in her/his mating decisions, e.g., by devaluing the prospective stepparent. Another strategy for children is to sabotage this new relationship by inflicting costs on the stepparent or on themselves which could drive the stepparent away. Some of these strategies are drug use, delinquent behaviors, or suicide attempts. Correspondingly, empirically living in a stepfamily (vs. living with two genetic parents) doubles the child's risk of engaging in delinquent behavior (Duntley 2016). It is hypothesized that the costs of a delinquent stepchildren deter the potential stepparent from this new relationship.

Conclusion

Currently, there is very few research about how the presence of children alter mate preferences (see also Goetz, *Mate Preferences After Having Children*), and much of the evidence presented here is rather indirect. Preferences for partners who are willing to invest and not abusing the children are likely to be more important in the presence of children, especially in mothers. Further, it is possible that children actively manipulate mating decisions of their parents in prospective stepparents. However, most of these predictions should be investigated more directly in the future.

Presence of Siblings

Definition: Alloparents

Introduction

In every century, promoting siblings and sibling relationships has been an integral part of families, societies, and cultures. The portrayal of siblings in folklore, mythology, religious texts and stories, books, cartoons, TV shows, and movies has suggested a standard message to siblings and families, “United we stand, divided we fall.” perhaps because sibling relationships can be the most intimate, yet conflictual relationships (Bank and Kahn 1982).

Over the years, depending on the cultural and family values, the definition of who is a sibling and who is not has changed. Therefore, siblings can include, but are not limited to, biological siblings, half/step-siblings, in-laws such as sisters/brothers-in-law, adopted siblings, foster

siblings, cousins, milk siblings, i.e., children nursed by the same female, God siblings, i.e., children of the Godfather or Godmother, friends who are like siblings, neighbors’ children who have grown together like siblings, coworkers, and more.

Despite the ambiguity in whether someone can be addressed as a sibling or not, there is ample evidence to conclude that siblings contribute tremendously in shaping one’s life trajectory. Hence, it is no surprise that sibling relationships are considered one of the closest and most long-lasting relationships (Bank and Kahn 1982; Cicirelli 1982), and sibling support is crucial at every stage of development (Whiteman et al. 2011). For example, evidence suggests that perceptions of positive sibling relationships are associated with higher self-esteem (Barnes and Austin 1995) and can be the most significant predictor of an individual’s adjustment in later life (Vaillant and Mukamal 2001). Overall, the sibling subsystem, “is the first social laboratory where children learn to negotiate, cooperate and compete with each other” (Minuchin, 1976 as cited in Perricone et al. 2014, p. 529).

Presence of Siblings and Life Span Development

In most cultures, especially with high maternal mortality rates, female kin members such as grandmothers, aunts, and sisters are often substituted as allomothers. In the absence of grandmothers and aunts, older sisters of newborn infants are intuitively considered “helpers at the nest” who assist their mothers in taking care of their younger siblings and household chores (Weisner et al. 1977). Notably, in cultures with high maternal and infant mortality rates, the presence of older sisters can significantly lower infant mortality rates (Sear et al. 2002).

Paradoxically, even in developed countries with lower maternal mortality rates, older siblings can be seen as an attachment figure (Ainsworth et al. 1978), a transitional object (siblings can use one another to make the transition away from the mother) or may help to support object relations (psychological processes that all people use early

in life to create internalized images of the self and other people) (Bank and Kahn 1982). Older children gain future life skills by interacting with their younger siblings, and younger siblings gain cognitive skills by imitating the older ones (Teti 1992). The mutual exchange of support and enhancement of skills in the early years may promote attachment, warmth, and the connection between siblings (Furman and Buhrmester 1985).

Over the adolescent years, sibling conflict increases (Brody et al. 1994), and sibling relationships may seem more autonomous, distant, and less emotionally intense (Cole and Kerns 2001; Scharf et al. 2005) as siblings try to act differently – aka sibling de-identification (Steinberg 2011). Nevertheless, positive sibling interactions still contribute to adolescents' academic competence, sociability, autonomy, and self-worth (Kim et al. 2007). In addition, higher perceptions of closeness with siblings were found to be linked with lower substance use (Samek and Rueter 2011). In minority families and collectivistic cultures, cultural norms may determine the implicit rules of the relationship and expectations (Cicirelli 1994) resulting in interdependence on each other. For instance, among African American families, reliance on siblings for support continues during the teenage years and caregiving responsibilities of younger brothers and sisters may promote resilience and the development of cultural identity (McHale et al. 2007).

In adulthood, siblings may serve as confidantes, teachers, role models, and friends and may provide help and support (Cicirelli 1982). Many adults continue to define themselves and measure their success in comparison to their siblings (Connidis and Campbell 1995; Milevsky 2005). Although professional and personal commitments may restrict frequent meetings with siblings, communication between siblings becomes meaningful and warm (Hamwey et al. 2019). Since the understanding between siblings grows stronger in comparison to the teenage years, sibling relationships are more intimate and less conflictual and can be a vital resource to fall back to at the time of traumatic life events such as divorce (Spitz and Trent 2018) or death of a parent (Kalmijn and Leopold 2019).

In older years, being the longest survivors of the family of origin, siblings become a valued repository of family memories and partners in shared reminiscence (Cicirelli 1982), and many may seek dependence on same-sex siblings for caregiving and support, with whom they have grown old with time (Mathur 2015). This dependence on siblings for caregiving and support during the older years may result in the resurfacing of any emotional conflict/emotional baggage from the early years carried by the caregiver (Bedford 1989).

It is important to state here that sibling caregiving is not limited to older years. Saxena et al. (2019), found that caregivers of individuals with disabilities were mostly younger adults, in their 20's, 30's and 40's. Moreover, the duration of caregiving provided by these sibling caregivers was reported to be equivalent to a part-time job.

Conclusion

The presence of siblings plays a vital role in the development of individual outcomes. Even though the definitions of siblings may vary in families and cultures, sibling relationships, for better or for worse, offer a unique opportunity to practice other relationships in a low-stake home environment. Besides, siblings shared history and environment, and lifelong commitment to supporting each other makes the relationship invaluable.

Preterm Birth

Patrick Abbot, Haley E. Eidem and
Antonis Rokas
Department of Biological Sciences, Vanderbilt
University, Nashville, TN, USA

Synonyms

Gestation; Premature birth; Prematurity; Preterm labor

Definition

Preterm birth is defined as babies born alive before the completion of 37 weeks of pregnancy.

Introduction

Preterm birth (PTB) is the leading cause of death in children under five worldwide and its complications are responsible for the deaths of approximately one million children annually. Babies born too soon are predisposed to suffer from neurodevelopmental, respiratory, gastrointestinal, and other complications throughout their lives. Both heritable and environmental risk factors contribute to PTB, and although PTB can be associated with medical disorders such as preeclampsia or intrauterine growth restriction, most cases of PTB occur spontaneously and lack an obvious

cause. Ultimately, why spontaneous PTB occurs in humans remains largely a mystery, but important clues can be found in the evolution of the traits and trade-offs that have shaped human pregnancy.

The Burden of Preterm Birth

PTB is a complex, multifactorial syndrome associated with multiple mechanisms of disease and many causes (Goldenberg et al. 2008; Muglia and Katz 2010; Romero et al. 2014; Vogel et al. 2018). Generally defined as birth before 37 weeks of gestation or 259 days since a woman's last menstrual period (Vogel et al. 2018), PTB can be caused by: (1) the medically indicated induction of preterm delivery due to either maternal or fetal complications, (2) preterm premature rupture of membranes (PPROM), or (3) spontaneous, idiopathic preterm labor with intact fetal membranes (sPTB). Approximately, a third of all preterm births are medically indicated due to preeclampsia (PE), intrauterine growth restriction (IUGR), gestational diabetes mellitus (GDM), chorioamnionitis, or other complications. Of primary concern for reducing rates of prematurity is understanding the causes of the remaining two thirds of preterm births occur in the absence of any obvious risk factors (Goldenberg et al. 2008; Vogel et al. 2018). PTB is a global problem with rates that range as high as ~18% in low-income countries to lower rates in high-income countries (~5%) (Blencowe et al. 2013), and a global prevalence around 10% (Vogel et al. 2018).

Efforts to reduce the rates of PTB have only met with mixed success. In the United States, for example, the rate of preterm birth has increased by 30% since 1981, reaching its peak at 12.5% in 2006, with the rate currently reported at 9.6% (Blencowe et al. 2013). Recent estimates indicate that complications of PTB are the leading causes of death of children below 5 years of age globally (Vogel et al. 2018). In what follows, we summarize some of the risk factors associated with PTB, and then address more ultimate questions about why variation in birth timing might occur in the

first place, which requires that we take an evolutionary perspective on birth timing. There are many reviews that discuss what is known about preterm birth from more molecular, clinical, and obstetrical perspectives, such as Goldenberg et al. (2008), Romero et al. (2014), Swaggart et al. (2015), Di Renzo et al. (2018), Strauss et al. (2018), and Vogel et al. (2018).

In one comprehensive review, Romero et al. (2014) summarized the growing consensus that PTB does not represent a single disease, but a syndrome with many causes. The causes of the PTB syndrome are complex with multiple genetic and environmental risk factors at play (Fig. 1). Epidemiological studies have linked poverty, education, age, body mass index, marital status, prenatal care, rates of multiple births, tobacco use, and other factors with PTB incidence

(Goldenberg et al. 2008). A particularly important risk factor for PTB is intrauterine infection: about one out of every four pre-term births is associated with infection (Romero et al. 2001). Intrauterine infections can cause PTB by activating the innate immune system and triggering the release of inflammatory proteins, such as cytokines and chemokines, that can lead to premature labor (Goldenberg et al. 2008). Maternal medical conditions that have been shown to increase PTB risk include thyroid disease, asthma, hypertension, diabetes, periodontitis, a history of prior preterm birth or cervical loop procedures, and depression (Goldenberg et al. 2008; Cobb et al. 2017). Finally, PTB risk has also been shown to be associated with maternal age, and women under 20 and over 40 are more likely to deliver preterm (Boardman 2008).

Preterm Birth, Fig. 1 PTB risk factors. Risk factors for PTB stem from genetics (pink), environmental stress (green), and ethnicity (blue). Redrawn from Bezold et al.

(2013) where relative risk and confidence intervals were obtained from previous independent PTB risk studies applying a variety of methods

There is clearly a role for genetics and epigenetics in PTB risk (York et al. 2014; Monangi et al. 2015; Strauss et al. 2018). Twin studies have demonstrated both maternal and fetal genetic contributions to PTB risk, with heritability estimated between 15% and 40% (Clausson et al. 2000; Treloar et al. 2000; Kistka et al. 2008). More recently, York et al. (2014) summarized the contribution of fetal (11–35%) and maternal (13–20%) genetic factors based on European and European-American datasets. A woman's risk of delivering preterm is increased if her mother, full sisters, or maternal half-sisters have delivered preterm (Boyd et al. 2009). PTB risk also differs between ethnic groups. For example, the PTB rate among black women in the United States is twice as high as the rate among white women, even after adjusting for other confounding factors (Adams et al. 1993; Collins et al. 2007; Kistka et al. 2007). Conversely, East Asian and Hispanic women have relatively low rates of PTB, whereas South Asian women have increased risk of low birth weight with no connection to PTB risk (Goldenberg et al. 2008). The factors contributing to the observed racial disparities in PTB rates remain unresolved, and although some of the racial disparities in PTB rates are likely to be genetic, both novel environmental risks and epigenetic factors may play important roles (York et al. 2014; Barcelona de Mendoza et al. 2017).

Not much is yet known about identifying the genetic variants that contribute to PTB risk, because most of the variants that have been discovered have either yielded conflicting results or have failed to be replicated (Strauss et al. 2018; Vogel et al. 2018). In a recent exciting development, Zhang et al. (2017) performed a genome-wide association study that led to the reliable identification of variants in six loci (*EBF1*, *EEFSEC*, *AGTR2*, *WNT4*, *ADCY5*, and *RAP2C*) that were significantly associated with gestation length and of variants in three loci (*EBF1*, *EEFSEC*, and *AGTR2*) that were significantly associated with PTB, opening the door for functional studies that shed light into the molecular mechanisms underlying PTB.

Long-term cohort studies have been particularly important in understanding the consequences of

low birth weight and preterm birth for adolescents and adults. An important longitudinal dataset known as the Helsinki Birth Cohort Study (HBCS) has provided many insights. The HBCS comprised 13,345 subjects from 1933 to 1944 with associated metrics that span prenatal to adult life. Another study that is beginning to yield results is the Born in Guangzhou Cohort Study, which has been tracking 33,000 Chinese babies and mothers since 2012. Data derived from the HBCS have provided important insights into the origins of disease in early life, including how low birth weight and premature birth increase risks of a variety of adolescent and adult diseases (Thornburg and Marshall 2015; Cyranoski 2018). Finally, some risk factors for PTB overlap with other inflammatory diseases such as inflammatory bowel disease or periodontitis, indicating strong gene x environment interactions that perturb general physiological and immunological processes involved in women's health (Strauss et al. 2018).

Clearly, many risk factors have been identified for PTB, but PTB remains disturbingly common. The majority of preterm births occur without any obvious risk factor and most risk factors are only weakly associated with PTB. Despite decades of effort, rates of PTB remain remarkably high or on the increase in many regions in the world, with variable patterns and etiologies that defy easy explanation (Byrnes et al. 2015; Vogel et al. 2018). One of the fundamental challenges in mitigating the risk of PTB is that the distinction between normal labor and prematurity is likely extremely subtle, and common pathways are at work in each (Romero et al. 2006). (Fig. 2). In the case of normal term labor, parturition is the result of complex uterine and extra-uterine factors (e.g., hormones) that physiologically activate “parturition complex cascade” (Di Renzo et al. 2018). In the case of premature labor, these same factors are disrupted, and as Romero et al. (2006) put it, are activated in a manner that can be described as “extemporaneous.”

This implies that understanding human gestation timing and PTB is tantamount to understanding not only human pregnancy but because pregnancy research involves animal models,

Preterm Birth, Fig. 2 Human pregnancy timeline. Normal human pregnancy lasts approximately 40 weeks. Delivery is considered preterm before 37 completed weeks of gestation

mammalian pregnancy more generally (Carter 2007; Phillips et al. 2015; Swaggart et al. 2015; Eidem et al. 2017). This is an enormous task, and the challenge of resolving PTB is entangled in the remarkable complexity of pregnancy itself. For example, pregnancy is the only physiological process where the cells of two genetically distinct individuals of the same species come into such prolonged and intimate proximity. In order to succeed, it requires elaborate physiological cooperation and coordination between mother and child, under conditions that range from the adverse to benign. Unexpectedly however, pregnancy is riddled with indications of difficulties and conflict. Less than 50% of conceptions result in pregnancy in humans, a rate higher than other mammals (Macklon and Brosens 2014). More dramatically, pregnancy remains one of the leading causes of female mortality worldwide. In

2013, the United Nations and World Health Organization estimated that a woman died about every 2 min from causes related to pregnancy or childbirth (Say et al. 2014). Although there are diverse causes, chief among them are excessive bleeding after childbirth, high blood pressure during pregnancy (pre-eclampsia and eclampsia), and difficult childbirth (Say et al. 2014), much of this can be pinned on (1) the deeply invasive nature of placentation in humans, and (2) the unusually large size of encephalized fetus at birth. As described in more depth below, both have important implications for understanding birth timing in humans (Rosenberg and Trevathan 2002; Dunsworth and Eccleston 2015). The common pathways that underlie pregnancy and PTB, and the unique features of human pregnancy, mean that understanding PTB requires a broad consideration of the evolution of pregnancy itself.

Human Pregnancy, in Brief

Humans are viviparous mammals – they have live birth. Live birth is not unique to humans or to mammals, however (Abbot and Rokas 2017). Viviparity has evolved over 150 times independently in vertebrates alone and occurs in invertebrates as well (Blackburn 2014; Wagner et al. 2014). Viviparity requires the development of means to nourish developing embryos and channel waste products away within the mother's body, and all eutherian mammals express *placental matrotrophy* – embryonic provisioning by maternal secretions by way of a transient, vascularized organ that attaches to the endometrial lining of the maternal uterus known as the placenta (Trexler and DeAngelis 2003; Fig. 3). In eutherian mammals, the placenta accomplishes many of the fetal functions performed by the major organs in newborns, including exchange of oxygen and carbon dioxide, the secretion of endocrine, growth factors, and cytokines, and the transport of nutrients and elimination of wastes (Burton and Fowden 2015; Nelson 2015). The eutherian placenta also has important endocrine functions as well, modulating maternal metabolism and the immunological response to pregnancy, while maintaining uterine quiescence (De Bonis et al. 2012). The centrality of the placenta is highlighted by the fact that, in the very

first days following fertilization, the majority of embryonic cells in the growing blastocyst are placental (Norwitz et al. 2001). The *chorioallantoic* placenta of eutherians is so-called because, soon after the blastocyst implants into the uterine wall, the fetal membrane that forms the embryonic bladder and stores fetal excretions, or allantois, fuses with and vascularizes the chorion, the outermost membrane involved in gas exchange that surrounds the embryo (Fig. 4).

Following conception, implantation of the blastocyst in the uterine endometrium involves penetration by the embryonic trophoblast (the precursor to the placenta) onto the uterine endothelial cells (Schlafke and Enders 1975). In most mammals, blastocyst implantation is shallow and superficial, and six tissue layers separate maternal and fetal blood (Gundling and Wildman 2015). In some however, including humans, the blastocyst embeds deeply and is engulfed interstitially by the maternal endometrium. Placental traits widely vary between mammalian groups (Martin 2008). In the *hemochorial* placenta of primates, rodents, and bats, the placental trophoblast cells invade the uterine lining, eroding and remodeling vascular tissues, facilitating the bathing of placental villi in maternal blood (Gundling and Wildman 2015; Burton et al. 2016). In humans, placentation is particularly invasive, and the remodeling of maternal blood vessels is exaggerated (Burton

Preterm Birth, Fig. 3 The tissues of pregnancy. Note that some tissues are of maternal origin (cervix, myometrium, decidua, and maternal blood; shown in red), others are of fetal origin (fetal blood, fetal membranes, umbilical cord, and placenta; shown in blue), and one is of mixed maternal and fetal origin (basal plate; shown in purple)

Preterm Birth, Fig. 4 Pregnancy uniquely requires communication and coordination across multiple tissues in two individuals. Multiple maternal tissues (written in purple font) and fetal tissues (blue) as well as tissues comprised of both maternal and fetal cells (orange) must interact to facilitate a healthy pregnancy. The placenta serves as the nexus of communication that links multiple tissues in the mother and fetus both locally and at a distance. For

example, interactions between NK cells in the decidua and fetal trophoblast cells in the placenta shape the degree of placental invasiveness and rate of the exchange of nutrients and oxygen. Similarly, the hypothalamic–pituitary–adrenocortical (HPA) axis communicates maternal and fetal stress levels across multiple tissues through cortisol shared through blood exchange in the placenta

et al. 2016). When maternal arterial remodeling is poor, reduced uteroplacental arterial flow to the placenta is followed by a cascade of potential consequences in response to fetal signals of distress, including inflammation, hypertension, kidney damage, and proteinuria in the mother, and an increase in oxidative stress and spontaneous PTB in the fetus, with a poor prognosis for both mother and fetus if untreated, and potentially life-long consequences for survivors (Redman and Sargent 2005; Thornburg and Marshall 2015). On the other end of the spectrum, the leading cause of maternal mortality is postpartum hemorrhaging (PPH), which results from improper separation of the placenta from the uterine wall, leading to massive maternal blood loss (Abrams and Rutherford 2011). PPH rarely occurs in mammals, and the degree with which it occurs appears

unique to humans (Abrams and Rutherford 2011). Abrams and Rutherford (2011) summarize evidence that suggests that PPH results from an overly aggressive placental invasion and vascular remodeling of maternal tissues, increasing the chances of impaired separation. Preeclampsia and PPH are but two of many disorders of pregnancy resulting from improper placentation, and as discussed further below, evolutionary perspectives provide unique insights into the factors that have led to the delicate maternal/fetal balance, and the complexities of birth timing (Abrams and Rutherford 2011; Thornburg and Marshall 2015).

Parturition involves a transition in the maternal myometrium from a state of anti-inflammatory quiescence to a pro-inflammatory contractile state. How this is accomplished varies

across mammals, but generally involves dynamic interactions between pro-inflammatory prostaglandins and the inflammation-suppressive effects of the steroid hormone progesterone (P4) (Swaggart et al. 2015). In humans, apes, and monkeys, P4 production is high throughout pregnancy and acts to repress pro-inflammatory genes. Towards the onset of parturition, increased expression of microRNAs (miR-200 family) induce functional progesterone withdrawal, the de-repression of inflammatory chemokine and cytokine pathways, and the production of contraction-associated proteins such as oxytocin and prostaglandin receptor (Di Renzo et al. 2018). Cervical ripening and changes in maternal inflammatory/proteolytic factors in decidual and uterine membrane mark the withdrawal of decidual support for pregnancy, culminating in membrane rupture and the onset of vaginal birth (Di Renzo et al. 2018). Preterm birth involves congenital or acquired agents that distort or disrupt this common template.

With respect to the evolution of pregnancy, there are two key trends. First, pregnancy-related genes and phenotypes have changed dramatically fast over evolutionary time and have often evolved independently, giving rise to convergence (Wildman et al. 2006; Wildman 2011; Wagner et al. 2014). The high evolutionary rate and convergence make studying the evolution of human pregnancy particularly challenging, because similarity in pregnancy phenotypes among distant relatives cannot be assumed to reflect the ancestral phenotype. For example, hyraxes, like humans, have highly invasive placentas, whereas elephants and lemurs have noninvasive ones, even though humans and lemurs are closer relatives to each other than to hyraxes and elephants (Wildman et al. 2006). Equally, there is variation in endocrine patterns as well. Levels of the hormone progesterone rise throughout gestation in humans and the great apes, but not in closely related Old World monkeys, nor in other mammals generally (Carter 2007; Grigsby 2016). What these patterns indicate is that even close evolutionary affinity cannot be used to infer similarity in phenotype (Swaggart et al. 2015).

Evolutionary Perspectives on Birth Timing in Humans

The persistence of complex heritable diseases like PTB that causes reproductive deficiencies or even untimely death is paradoxical, because these diseases seem to favor their own demise (Brown et al., 2013). Why is there heritable variation in birth timing in humans? Evolutionary perspectives on medicine are predicated on the idea that human diseases emerge out of the evolutionary challenges inherent to fitting complex biological systems to diverse and shifting optima (Gluckman and Hanson 2006; Nesse et al. 2012; Stearns and Medzhitov 2015). Nesse et al. (2012) outline six broad and interrelated categories of evolutionary explanations for traits that predispose humans to noncommunicable diseases. We highlight three of these for PTB. The first is **mismatch** between our biological legacy and our modern environments, as in the case of diaper rash (Gluckman and Hanson 2006; Corbett et al. 2018). Mismatch between our biological designs for ancestral environments and modern lifestyles accounts for many common diseases such as obesity, addiction, diabetes, or heart disease. Disruption of normal pregnancy may reflect a mismatch between our modern lifestyles and our biological designs. A second explanation, related to evolutionary constraints, is that of **trade-offs**, the idea that there are combinations of traits that cannot be simultaneously optimized by natural selection (Ricklefs and Wikelski 2002; Stearns and Medzhitov 2015). For example, many fitness-related traits draw on common energetic reserves, and investment in one comes at the expense of the other (Zera and Harshman 2001). An example is large body size, which may improve survival, but comes at the expense of numerical investment in reproduction. Finally, a third explanation is that of **evolutionary conflicts**. All multicellular organisms are aggregates of genes, cells, tissues, and organs; natural selection can act differently on any individual member or level, giving rise to evolutionary conflicts (e.g., a mutation that may favor cell division and propagation of the gene that carries it may not be advantageous for the tissue or organ, as in cancer) (Queller and Strassmann

2018). Conflicts over pregnancy may be particularly acute in humans, because of the invasive nature of placentation and that natural selection can act differently in parents versus offspring. Below, we consider each of these explanations in more depth.

Mismatch and PTB

Some environmental influences on birth timing, such as tobacco use, represent modern causes of PTB that can be thought of as mismatches between the conditions our pregnant bodies were designed for, and the ones that our modern lives too often provide (Crump et al. 2011; Corbett et al. 2018). Many environmental risk factors probably fall in the category of causes that almost certainly emerged within modern times, and to which humans are poorly adapted. For mismatches that affect the outcome of normal pregnancy, there should be selection for traits that protect against maternal or fetal harm. Indeed, there is evidence not only that humans have experienced on-going natural selection on pregnancy-related traits but evidence of population-specific variation as well (Brown et al. 2013). An illustrative example can be found in preeclampsia (Ben et al. 2016). Modern changes in diet and nutrition may be a source of “mismatch” between contemporary diets and maternal physiological adaptations for pregnancy. Risk for preeclampsia varies inversely with salt intake, and paradoxically, rates of preeclampsia are low in countries such as Japan and Iran, where salt-intake is high (Brown et al. 2013). Brown et al. (2013) suggest that women in high salt-intake countries may have experienced selection for insensitivity to high-salt diets, conferring some protection against preeclampsia. In the absence of such insensitivity, the high-salt diets characteristic of Western societies represent evolutionary mismatches with potentially severe consequences for affected pregnant women. Like preeclampsia, PTB also exhibits population-specific, ethnic and racial variation similar to preeclampsia, raising the hypothesis that mismatches contribute to its high incidence.

One intriguing pattern is that it is not clear whether several of the known, important environmental risk factors for PTB, such as maternal

nutrition and stress, represent entirely modern perturbations of pregnancy. In a meta-analysis of 78 studies on maternal body mass index (BMI), Han et al. (2010) showed that low maternal BMI was associated with increased risk of both PTB and low birth weight. Likewise, in a systematic review of 39 studies, Staneva et al. (2015) concluded that psychosocial factors, such as maternal stress during pregnancy, can have a profound effect on birth outcomes. Glucocorticoids increase towards the end of pregnancy and are important for maturation of fetal organs. However, maternal stress can elevate glucocorticoids, which cross the placenta and result in reduced fetal growth rates (Thornburg and Marshall 2015). There is also evidence of racial differences in stress-induced inflammatory responses that are linked to PTB risk (Christian et al. 2013). In animal models, both nutrition and stress have adverse effects on birth outcomes. In rodents for example, various forms of stressors, from hypoxia to social stress via dominance interactions with conspecifics, can result in reduced litter sizes, smaller birth weights, selective reabsorption/abortion of fetuses, and various alterations of fetal developmental programs with adverse postnatal effects in offspring (Brunton 2013). While the mechanisms underlying these effects are not fully understood, conserved elements of the vertebrate neuroendocrine systems that regulate response to stress (e.g., the hypothalamo-pituitary-adrenal or HPA axis) are centrally involved.

That adverse pregnancy outcomes could display such sensitivity to environmental variation, mediated by broadly conserved vertebrate stress responses, has led to various evolutionary hypotheses that propose adaptive maternal/fetal mechanisms for inducible plasticity in birth timing (Gluckman and Hansen 2006). Plants and animals can alter phenotypic traits in response to environmental cues, a phenomenon known as *phenotypic plasticity*, and this can happen not only in adults but over the course of development as well (Via and Lande 1985). Crespi and Denver (2004) draw on abundant evidence for phenotypic plasticity in animals, encoded by conserved genetic and physiological mechanisms that predate modern human origins, to propose that at least some of the

Preterm Birth, Fig. 5 Within species variation in gestation length among representative primates and mammals. Boxes denote the range of values encompassed by 1 standard deviation from the mean in either direction; whiskers

extend to 3 standard deviations. The dotted line corresponds to 92.5% completed gestation time. (References for each species' data can be found in Phillips et al. (2015))

variation in birth timing in humans might reflect similar plastic responses to environmental input. Indeed, variation in birth timing is the rule, not the exception, in animals (Phillips et al. 2015) (Fig. 5). The mammalian HPA axis matures during the third trimester in humans, with a rise in stress hormones that regulate fetal development and prepare the maternal and fetal membranes for parturition (Crespi and Denver 2004). The months leading up to parturition are characterized increasingly by a finely-tuned period of stress sensitivity. In this view, both maternal and fetal fine-tuning of the rate of fetal development and/or parturition in response to such factors as nutrition or stress might reflect a form of adaptive plasticity in birth timing. To the extent that pregnancy is costly and that its costs vary with external conditions, maternal and fetal mechanisms may be present for navigating the course of pregnancy in a way that minimizes those costs, especially in conditions in which pregnancy outcomes are uncertain (McLean et al. 1995; Wells 2003; Pike 2004). Haig (2008) has suggested that mother and fetus may differ in plastic adjustments to gestation

length, depending on environmental conditions. Romero et al. (2014) make a similar point, that PTB in response to intra-amniotic infection likely has some survival value for both fetus and mother. Thus, it seems reasonable to hypothesize that some adverse birth outcomes, including some cases of PTB, may be due to mismatch between conditions that alter the maternal microbiome and birth outcomes (Chu et al. 2018). The major etiological roles of vaginal, intrauterine, and periodontal infections in PTB, and the organizing role of maternal inflammatory/immunological responses in pregnancy and labor, strongly implicate a microbial x environment interaction in pathologies of pregnancy. Indeed, four of the loci identified by Zhang et al. (2017) with variants conferring risk for gestation length or PTB, two (*EBF1* and *EEFSEC*) likely are involved in inflammatory pathways, albeit indirectly (Romero et al. 2006; Strauss et al. 2018).

In summary, an evolutionary restatement of the “common pathway” hypothesis for PTB could be as follows: PTB is the result of a mismatch between ancient, conserved biological

mechanisms for orchestrating of birth timing in viviparous mammals in response to once-reliable cues that are now absent or miscalibrated by modern lifestyles.

Trade-Offs and PTB

Evolutionary anthropologists have long hypothesized that two human traits interact to determine birth timing (Trevathan 2015). One is our big brain size, which has resulted in remarkably encephalized infants at birth relative to other primates. The other is our bipedalism, which has resulted in the remodeling of our pelvic girdles to accommodate our upright stance. Trade-offs and constraints lie at the root of a branch of evolutionary biology known as *life history theory* (Zera and Harshman 2001; Ricklefs and Wikelski 2002; Roff and Fairbairn 2007). Life history traits are those that characterize the patterns of organism survival and reproduction, such as age at first reproduction and body size. A tenet of life history theory is that these traits are interrelated and often negatively correlated. Large body size may increase offspring survival probabilities, for example, but it comes at the expense of risking dying before reproducing, since large bodies take longer to build. Natural selection is assumed to act on life history traits collectively, as if they each were constrained by the competing demands of the others, and the solution is a compromise.

With respect to birth timing in humans, one leading hypothesis, known as the *Obstetric Dilemma* (OD), is that gestation length is governed by a trade-off between brain size and pelvic proportions, and occurs at the point at which the head of a big brained fetus can barely fit through the narrow pelvic girdle of a bipedal-adapted female (Wells et al. 2012). This is proposed to account for the observation that, among primates, human neonates are particularly developmentally immature, with brain to body ratios the smallest among all primates (Rosenberg and Trevathan 2002). More recently, a competing hypothesis, known as *Energetics of Gestation and Growth* (EGG), argued that birth timing is set by the point at which it becomes metabolically inefficient for the mother to nurture the fetus

within her uterus relative to the provision she could accomplish after birth (Dunsworth et al. 2012). Both hypotheses invoke constraints and trade-offs in the ability of mothers to optimize neonate development in utero. The key point is that for any trait governed by trade-offs, outcomes can be precariously balanced between opposing demands, and changes to one demand can result in pathological over- or under-compensation in the others (Crespi 2010; Crespi and Go 2015; Queller and Strassmann 2018). If PTB is governed by trade-offs, the implication is phenotypic variation in birth-timing may be maintained because of how biotic and spatio-temporal variation affects the functional compromises required during pregnancy.

A particularly important trade-off in animals is between immunity and other energetically expensive traits, such as growth or reproduction. Maintaining or mounting immune and inflammatory responses comes at a cost to other physiologically demanding needs. Immunity trade-offs can have profound effects. For example, Urlacher et al. (2018) showed that in a population of Amazonian forager-horticulturalists, children who experience only mildly elevated immune responses can have as much as a 49% reduction in growth rate, resulting long-term differences in stature and likely other developmentally dependent traits. Such direct effects of immunity and inflammatory responses on human phenotypes may have particular relevance to pregnancy and birth timing.

As described above, mammalian reproduction has been superimposed on ancestral immune factors, which have been co-opted for key roles in the relatively more recent development of internal fertilization, placentation, and gestation (Abrams and Miller 2011; Bainbridge 2014). Early views on the role of immunity in pregnancy centered on the idea that the maternal immune responses must be suppressed in order to tolerate pregnancy, an observation that formed the rationale for Medawar's famous *allograft model* for mammalian pregnancy in which antigenically foreign fetal membranes are like grafts onto maternal tissues, requiring mechanisms for tolerance (Medawar 1953). While Medawar's model captured

elements of the immunological challenges posed by the particularly long gestation involved in human pregnancy (Bainbridge 2000), the modern view of the role of the maternal immune system in mammalian pregnancy is dramatically different. Inflammatory and immunological pathways are central to understanding the mechanisms that determine birth timing and parturition in humans (Moffett and Loke 2004; Trowsdale and Betz 2006; Abrams and Miller 2011; Mor et al. 2011; Romero et al. 2014). Maternal immunity first and foremost must protect against infections and pathogens. However, human reproduction involves cycles of up and down-regulation of immunological and inflammatory factors governed by reproductive hormones (Abrams and Miller 2011; Alvergne and Tabor 2018). Over the course of pregnancy, dynamic shifts in immunity are required for successful pregnancy (Abrams and Miller 2011). Fetal tolerance is promoted by the absence of MHC alloantigens on the fetal trophoblast cells. At the same time, the early stages of pregnancy bear many of the hallmarks of tissue injury, including a sustained maternal inflammatory response that underlies the all-too-familiar morning sickness (Macklon and Brosens 2014; Griffith et al. 2017; Ashary et al. 2018). Pro-inflammatory cytokines that induce cell-mediated immunity are down-regulated during pregnancy, leaving pregnant women more vulnerable to infectious diseases (Abrams and Miller 2011). Placental inflammatory responses vary with maternal body mass (Thornburg and Marshall 2015). With the onset of labor, increased catabolism of progesterone, which suppresses the inflammatory response, is associated with a dramatic increase in inflammation, including the invasion of leukocytes into the myometrium, cervix, and feto-placental membranes (Abrams and Miller 2011). These shifts in maternal immunity over the course of pregnancy underlie the critical role that trade-offs between the dual and sometimes competing roles that immunity plays in female health and reproduction (Romero et al. 2001). Little surprise then that inflammatory pathways, and genetic variants that disrupt the carefully choreographed involvement of inflammation in normal labor and birth, are emerging as prime

candidates for understanding the causes of spontaneous pre-term birth (Strauss et al. 2018).

Evolutionary Conflicts and PTB

Pregnancy should seem to be an entirely communal enterprise between mother and fetus. However, because of viviparity, placental traits reflect an evolutionary tug-of-war between parents and offspring over resources (Haig 1993). Matrotrophic nourishment in viviparous species implies that a developing fetus can negotiate with its mother over nutritive provisioning, something not possible in egg-laying species. An inevitable conflict arises in such cases, because in sexually reproducing species, the fetus only shares half of its genes with its mother, and in mammals that are not monogamous, less than half its genes with any future offspring that its mother may have. Mothers, on the other hand, are equally related to all of their offspring. Thus, the investment optima for mother and offspring can differ, with mothers maximizing total reproductive effort and each offspring favoring greater personal investment. The *viviparity conflict hypothesis* holds that many features of viviparity bear that signatures of parent-offspring conflict (Crespi and Semeniuk 2004). Indeed, as Crespi and Semeniuk (2004) point out, when the costs and benefits of matrotrophic viviparity are considered objectively, for offspring the benefits of starting out life nourished and sheltered within the uterus seem obvious, such as greater size and vigor at birth or avoidance of predation common to egg-laying species, and the costs few. But for mothers, the reverse is true. The direct apposition of maternal and fetal tissues over development thus seems designed for the benefit of offspring, by providing the most efficient means of resource transfer.

Conflicts of pregnancy are most easily recognized in live-bearing animals, where dramatic examples such as intrauterine cannibalism found in various amphibians, sharks, and fish or selective abortion of excess, small, or impaired embryos can be found in many animals, including primates (Forbes 1997; Crespi and Semeniuk 2004; Catalano et al. 2018). In the case of selective abortion, the data are so abundant due to

decades of selective breeding and work with laboratory models that it is known as *The Bruce Effect*, named after the researcher who first described adaptive reproductive suppression and selective abortion in pregnant females under conditions that signal declining prospects for gestating young (Catalano et al. 2017). Although controversial, the existence of a Bruce Effect in humans (spontaneous abortion of *perivable* infants before the 28th week of gestation) is supported by non-random patterns in spontaneous abortions, such as selection against morphologically, genetically, and chromosomally abnormal fetuses (Catalano et al. 2018). The larger implication is that gestation timing is not the result of a fixed program, but rather dynamic and highly sensitive to crosstalk between mother and infant informed by numerous inputs, including fetal health. As Catalano et al. (2018) put it, parturition in humans may be “strategic.”

Conflict theories of pregnancy thus hold that mothers and infants can have opposing strategies. Recognizing this sheds light on many puzzling features of pregnancy, each with implications for understanding gestation timing and PTB (Haig 1993, 2008; Crespi and Semeniuk 2004). Some of these include: (1) the placental production of fetal hormones and other factors that manipulate maternal physiology and nutrient transfer, in many cases seeming to wastefully duplicate those produced maternally (Haig 1993); (2) evidence of maternal inactivation of placentally secreted factors (Haig 1993); (3) a shift in the production of pregnancy-promoting progesterone at 5–7 weeks of pregnancy from maternal ovary to the placenta, which is uncommon in other mammals (Pavličev and Norwitz 2017); (4) evidence of maternal mechanisms to regulate placental invasiveness (Heap 1994; Moffett and Loke 2004); (5) the rapid evolution and multiple independent origins of placental traits, including multiple origins and evolutionary convergence of invasive placentae, implying strong and ubiquitous selection, fast and positive selection on placental or maternal genes and genome features involved in pregnancy, and the evolutionary reversion from invasive to less invasive placental types (Crespi and Semeniuk 2004; Wildman et al.

2006; Hannibal et al. 2014); and (5) the observation from many viviparous species that offspring size is governed in part by offspring genotype and is not solely under maternal control (Furness et al. 2015).

With respect to this last example, perhaps most convincing is the observation of *genomic imprinting* of genes expressed in the eutherian placenta, many of which are involved in nutrient transfer across the maternofetal interface (Frost et al. 2010; Monk 2015). Genomic imprinting is characterized by monoallelic, parent-of-origin gene expression, which is mediated by various epigenetic mechanisms acting both prior to and after fertilization (Peters 2014). In vertebrates, it occurs in therian mammals (marsupials and eutherian mammals) and is apparently absent in the oviparous monotremes (Renfree et al. 2009). Little more than a hundred genes are imprinted in humans, and many are associated with disease due to monoallelic expression or disruption of imprinting itself, implying strong countervailing selection (Peters 2014; Furness et al. 2015; Wilkins et al. 2016). Importantly, many imprinted loci are expressed early in development in tissues that are involved in nutrient transfer to developing offspring, and thus regulate growth (Babak et al. 2015; Wilkins et al. 2016). Numerous studies have demonstrated that paternally expressed alleles tend to promote fetal growth or other traits that promote maternal resource transfer, whereas maternally expressed alleles tend to inhibit growth (Furness et al. 2015; Wilkins et al. 2016). Interestingly, more genes are imprinted paternally than maternally, and in adult tissues, tend to be mostly expressed in the central nervous tissues, some of which affect maternal and social behaviors (Peters 2014; Furness et al. 2015). These patterns are consistent with the view of genomic imprinting as a form of genomic conflict (Wilkins et al. 2016). Alternative views, such as *co-adaptation theory*, hold that genomic imprinting coordinates the extraordinary complexity of sexual reproduction and fetal development between maternal, paternal, and fetal genomes (Wolf and Hager 2006).

The importance of genomic imprinting in pregnancy and early development bolsters the view

that birth timing is a delicately balanced compromise between genetic elements with competing strategic interests (Crespi 2010). In this tug-of-war view of pregnancy, the genomic background out of which birth timing emerges has the potential to greatly exacerbate the effects of environmental variation.

Conclusion

PTB is among the most serious and least understood challenges facing infant and adolescent health globally. Because of the singular complexity of pregnancy (Eidem et al. 2017), identifying the causes and remedies to PTB will require concerted efforts and close collaborations between scientists from diverse fields. The diverse perspectives offered by clinical, epidemiological, sociological, and evolutionary studies all shed light on the mysteries of human pregnancy, but it is evident that much more cross-talk will be required to understand the genetic and phenotypic causes of prematurity. A fundamental challenge will be developing opportunities for scientists from diverse fields to share perspectives, not all of which will have immediate clinical relevance.

Preterm Labor

► Preterm Birth

Prevalence of Forced Copulation in Orangutans

Amy M. Scott

Department of Anthropology, Boston University,
Boston, MA, USA

Synonyms

Forced matings; Resisted matings

Definition

The use of aggression or physical restraint by a male orangutan toward a female orangutan in the mating context.

Introduction

Before the 1980s, many orangutan researchers called forced copulations “rape”; however, this terminology has been replaced with the more accurate term “forced copulation.” Orangutans (*Pongo* spp.) are the only nonhuman primates who regularly exhibit forced copulations by males. Forced copulations have been observed in every study population of wild orangutans, as well as in rehabilitant and captive settings. Forced copulations are a form of sexual coercion, in which males use aggression to force a female to mate, when she is resistant to the mating attempt. Male orangutans are only physically aggressive toward females in the context of mating. When female orangutans resist matings, male orangutans may respond by pursuing, restraining, and attempting to force a female to mate.

Orangutan Background Information

Orangutans are semi-solitary, arboreal primates who live in tropical rainforests on the islands of Borneo and Sumatra in Indonesia and Malaysia. The primary social unit is an individual independent (adult or adolescent) orangutan or adult female with one accompanying dependent offspring. Offspring remain with their mother until they are 6–8 years old and start ranging independently around the time their mother gives birth to her next offspring. Orangutans form transient social groupings to forage together, to mate, or to travel together for a few hours or days. Male orangutans have two fully mature body morphs: flanged males and unflanged males. Flanged males are larger than unflanged males and exhibit secondary sexual characteristics: fatty cheek pads, enlarged throat sacs and the ability to produce long calls. The age at which males become

flanged is highly variable, and some males may never flange. Orangutans are sexually dimorphic in body mass. Flanged males are approximately twice the size of adult females, but unflanged males are approximately the same size as adult females.

Defining Forced Copulations

Forced copulations in orangutans are difficult to define because a single mating event may contain elements of both female proceptivity (active mating interest) or indifference, as well as female resistance and male aggression. Additionally, a single female may mate both cooperatively and resistantly with the same male in one day. Female orangutans display a variety of proceptive behaviors: approaching the male, spreading the legs of the male, inspecting male genitalia, and/or stimulation of penis manually or orally. Female resistance behaviors include vocalizing, running from a male, pulling away from a male, struggling against a male, and changing body positions to halt intromission. Female resistance behavior varies in degree, from a short push at the beginning of mating, to a prolonged struggle and the appearance of distress (vocalizations, defecation). Male aggressive behaviors in the context of mating include vocalizing, chasing, biting, hitting, pushing, pulling, or holding a female to force her into a mating body position. Interestingly, males are only aggressive in the mating context, and females never display injuries after a forced copulation.

Orangutan matings occur in trees and are often obscured from viewers by leaves and branches further complicating the characterization of matings. While many primate species have short matings characterized by stereotyped actions, orangutans mating events are prolonged, with male intromission lasting from 2 to 36 min (Knott 2009). The entire sexual encounter can last over an hour, and involve manual and/or oral stimulation by both male and female orangutans. Because of the orangutan’s large body size and their arboreality, there is often a lot of body repositioning required to

achieve intromission. Body position during mating often includes one or both individuals hanging from branches and may involve multiple body position (ventral-ventral, ventral-dorsal, and/or ventral-lateral). For all of these reasons, matings can be difficult to characterize as either solely forced or cooperative. However, it is clear that some orangutan matings do include elements of coercion or force.

Why Do Forced Copulations Occur?

Female resistance to matings is negative mate choice, not an effort to assess mate quality (Fox 1998). Female resistance and proceptivity are affected by a variety of factors, including the length of social interaction, male morph, female ovulatory status, and male rank stability. Galdikas (1985a, b) found that females are less resistant to mating when the male and female pair have been traveling together for an extended period of 3 or more days. The length of the time a pair travels together and female proceptivity may both be indicative of female preference. Knott et al. (2010) found that male morph and female ovulatory status predict female proceptive and resistant matings. During the periovulatory period, when females are most likely to conceive, females are more resistant toward unflanged males and are proceptive toward flanged males, and outside the periovulatory period, females are more proceptive toward all males (Knott et al. 2010). This indicates that female resistance is negative choice against undesired paternity by unflanged males. Flanges and the accompanying secondary sexual characteristics may be an honest signal of male quality, which may be the reason for female preference. Utami et al. (2002) found that there were fewer forced copulations during a period of male rank instability, when flanged males were vying for dominance. This may be indicative of a female strategy to spread paternity certainty more broadly when the male hierarchy is in flux. Both of these findings indicate that female orangutans employ a mixed mating strategy, mating with multiple males to spread paternity certainty,

but focusing mating on desired males when the chance of ovulation is highest. However, if flanged males are preferred mates, the mixed mating strategy does not explain why females ever resist matings with flanged males. Perhaps females resist matings to reduce the possibility of disease transmission or to reduce energetic costs associated with mating (Knott 2009).

The costs of forced copulations for female orangutans have not yet been quantified. Females are never injured during forced copulations (Knott 2009). Fox (1998) found that females had reduced feeding efficiency on days when they were social compared to days when they were alone, but there was no further reduction in feeding efficiency on days with forced copulations. Disease transmission is another possible cost (Knott 2009), which may be more pronounced for orangutans than other gregarious primates, but this hypothesis remains to be tested. The most likely cost of forced copulations is undesired paternity, but this remains to be demonstrated. Female resistance to forced copulation attempts by males is effective in preventing intromission (Fox 1998; Mitani 1985). Female resistance behaviors also reduce the length of a copulation, which may prevent ejaculation and, in turn, undesired paternity (Knott et al. 2010).

Forced and Cooperative Matings, by the Numbers

The prevalence of forced copulations varies by study site. Figure 1 shows the percentage of orangutan matings that are forced and cooperative at five different orangutan study sites. The rate of forced copulations during a study period ranged from 19% to 40% of all matings. The variation is likely to be due in part to variation in the percentage of males that are flanged versus unflanged at each study site, whether the study was focused on collecting data from a certain class of males or females, male rank stability during the study period, and the number of cycling females in the study site during the study period. Individual and population variation may also play a role.

Prevalence of Forced Copulation in Orangutans, Fig. 1 The proportion of forced and cooperative copulations in five orangutan populations. (Data from Gunung Palung from Knott (2009). Data from Ketambe combined from two nonoverlapping studies Schurmann and van

Hooff (1986) and Utami (2000). Data from Kutai from Mitani (1985). Data from Suaq from Fox (1998). Data from Tanjung Puting from one study period by Galdikas (1985a, b))

Why Are Forced Copulations Prevalent in Orangutans

The reason why forced copulations are prevalent in orangutans is not well understood. Palombit (2010) discusses and refutes previously suggested reasons for the prevalence of orangutan forced copulations: sexual dimorphism, lack of female social support, and an alternative male mating strategy. It has been suggested that forced copulations occur due to sexual dimorphism in body size but this does not explain why unflanged males are able to employ forced copulations or the lack of forced copulations in other sexually dimorphic primates. It has also been posited that a lack of female social support due to orangutans' solitary social structure may contribute to the prevalence of forced copulations. However, this does not explain the lack of forced copulations in other solitary primates or why humans who are highly social are the only other primate who exhibit forced copulations. Based on early field observations, it was suggested that forced copulations were an alternative mating

strategy employed by unflanged males. However, this does not explain the use of force by flanged males that has since been observed in subsequent studies. Rather, the potential for sexual conflict is high in orangutans and forced copulations are a manifestation of sexual conflict. The potential for sexual conflict is high, in part, due to the extreme incongruence in parental investment by males and females, which in turn leads to conflicting reproductive strategies between males and females. However, it remains unclear as to why this results in mating conflict and forced copulations in orangutans, but no other nonhuman primate.

Conclusion

Combining all the published data on wild orangutan copulations reveals that approximately one quarter of all orangutan matings are forced copulations (Fig. 1). Forced copulations are a behavioral manifestation of sexual conflict. Forced copulations by male orangutans are in response to

resistance by females, which is negative female choice. Female resistance is affected by many factors: male morph, female ovulatory status, male rank stability, and likely more factors that are not yet understood.

Definition

Sexually transmitted diseases (STDs) are infections caused by viruses, bacteria, or parasites that are transmitted through sexual contact, especially vaginal, oral, and/or anal intercourse.

Introduction

STDs are a prevalent and significant public health threat affecting more than 20 million people in the USA yearly, with an associated economic burden exceeding 16 billion dollars in direct medical costs (Owusu-Edusei et al. 2013). STDs are associated with a number of signs and symptoms, potential subsequent morbidities, and even mortality. Preventive efforts are therefore needed to alleviate the burden of STDs, especially among higher-risk groups. This entry summarizes the prevalence and incidence trends of some of the most common STDs, as well as the most common morbidities associated with STDs. Human immunodeficiency virus (HIV) will not be included in this analysis given the special epidemiological factors and biological characteristics differentiating this condition from other STDs. Ultimately, through this entry, we aim to highlight the importance of STD prevention as a public health priority.

Scope of the Problem

According to the CDC annual STD surveillance report (CDC 2017), the three nationally reported STDs, i.e., chlamydia, gonorrhea, and syphilis, have reached an all-time high of two million new cases in 2016.

Chlamydia trachomatis was ranked as the most common notifiable condition in the USA in 2016, with more than 1.5 million cases reported. Between 2006 and 2016, the rate of chlamydial infections increased by 55%, though it remains 3.5 times lower than the historical peak of 464.1 per 100,000 population reached in 1975 (CDC 2017). This recent surge in incidence reflects potential changes in sexual behavior such as age at sexual debut and economic and sociodemographic factors such as decrease in marriage rate and delayed child-birth (Fenton and Lowndes 2004) as well as an improvement in screening. Chlamydia incidence is two times higher among women compared to men. Women aged 20–24 have the highest incidence rate of 3779 per 100,000 population. Similarly, the prevalence of the disease is highest among women (2.0% vs. 1.4% in men) and young people aged 20–24 (2.9% compared to 2.4% in age group 14–19 and 1.1% in age group 25–39) (Torrone et al. 2014). Considerable racial disparities exist in chlamydial infection with Black/African Americans having the highest rate of infection, more than five times greater than Whites (CDC 2017).

Gonorrhea is the second most common notifiable STD in the USA. Chlamydia and gonorrhea coinfection might explain the similar trend observed in both STD rates in the USA in recent years. Like Chlamydia, the rate of gonorrhea is increasing, mostly affecting young people and African Americans. After having reached a historic low of 98.1 per 100,000 population in 2009, the incidence rate of gonorrhea increased by 48.6% in 2016. Young people are at the highest risk for gonorrhea infection with an incidence rate of 510.2 per 100,000 persons for 20–24-year-old youth followed by 381.8 per 100,000 people aged 15–19 years old in 2016. Incidence of gonorrhea is highest among Black/African American people, particularly young African American men and women. For instance, the incidence among

African Americans is more than 17 times higher than that of Asians, the racial group with the lowest rate of gonorrhea infection (CDC 2017).

Non-congenital syphilis cases are medically classified into three main stages, primary syphilis characterized by the appearance of ulcers or chancre at the infection site, secondary syphilis with signs including skin rash and mucocutaneous lesions among others, and tertiary syphilis with more severe manifestations such as formation of gummas in vital organs, loss of coordination of movement, progressive dementia, paralysis, and even death. The incidence rate of primary and secondary syphilis increased by 17.6% in 2016 compared to the previous year to reach 8.7 cases per 100,000 population (CDC 2017). Young people aged 25–29 years old have the highest rate of reported primary and secondary syphilis infection (27.5 per 100,000 population). Primary and secondary syphilis are particularly concerning among men who have sex with men (MSM) who constitute the vast majority (80.6%) of cases while forming only 3.9% of the national population (Grey et al. 2016; CDC 2017).

With more than 40 distinct strains, human papillomavirus (HPV) is the most common sexually transmitted infection. Unlike other STDs, HPV prevention can be achieved through vaccine administration. In 2006, the Center for Disease Control and Prevention recommended vaccination of females under the age of 6 against HPV. Two main vaccines are used to target different numbers of high-risk HPV types, the quadrivalent and the 9-valent HPV vaccine. Comparing the pre-vaccine era (2003–2006) to the post-vaccine era (2009–2012), the prevalence of cervicovaginal HPV among women aged 14–19 years old declined by 64% (from 11.5% to 4.3%) and that of women aged 20–24 years old decreased by 34% (from 18.5% to 12.1%) (Markowitz et al. 2016). In light of its encouraging effectiveness in HPV prevention, there continues to be considerable opportunity for improving vaccine uptake nationwide. Trichomonas is a sexually transmitted infection caused by a protozoan called *Trichomonas vaginalis*. The prevalence of trichomonas infections in the USA remains relatively steady since the year 1990, with 139,000 physician office

visits in 2015. It is worth noting that since HPV and trichomonas are not nationally notifiable conditions, estimates of prevalence and incidence of these STDs are accompanied by a margin of error due to the methodological limitations of the studies yielding these figures.

Subsequent Morbidities of STDs

The clinical manifestations of STDs fall into a broad spectrum spanning from discomfort due to genital itching, odor, and discharge to life-threatening subsequent morbidities and comorbidities.

Chlamydia and gonorrhea are two preventable causes for infertility and ectopic pregnancy due to pelvic inflammatory disease (PID). When left untreated, chlamydial infection causes PID in 10–15% of infected women (CDC 2015). Most women who are infected with Chlamydia and gonorrhea are symptomatic, that is, they will show no symptoms, which underlines the need for routine testing for young women and women at high risk, as recommended by the CDC (CDC 2015).

Untreated cases of syphilis infection can progress into tertiary syphilis, a lethal condition that can affect the nervous, circulatory, and musculoskeletal systems. The invasion of the nervous system, called neurosyphilis, can cause paralysis and dementia among other neural symptoms. Ocular syphilis can cause a range of eye-related conditions ranging from vision changes to permanent blindness (CDC 2015). Untreated syphilis in pregnant women can be transmitted to the fetus through the placenta causing congenital syphilis. Congenital syphilis results in obstetric complications like premature birth, low birth weight of newborn and miscarriage, as well as fetal malformation and stillbirth (CDC 2015).

The oncogenic subtypes of human papillomavirus (HPV) cause virtually all cases of cervical cancer. Cervical cancer accounted for more than 12,500 new cases and 4,115 deaths among women in 2014 (US Cancer Statistics Working Group 2017; Walboomers et al. 1999).

Aside from the numerous subsequent morbidities related to STD infection, STDs increase the risk for acquiring HIV. HIV-negative heterosexual people and men who have sex with men who are infected with an STD are twice more likely to acquire HIV during sex with an HIV-positive heterosexual partner (Hughes et al. 2012). The association between STD infection and increased HIV susceptibility is biologically plausible due to the presence of STD-caused genital inflammation and ulcers that could facilitate HIV transmission (Fleming and Wasserheit 1999). The evidence supporting this relationship has led to a major shift in prevention interventions, now leaning toward incorporating mutually reinforcing STD and HIV preventive efforts (Fleming and Wasserheit 1999; Hayes et al. 2010).

STD Prevention

To reduce the burden of STD infections, it is important to understand the risk and protective factors involved and to implement targeted interventions for higher-risk groups (DiClemente et al. 2009). The risk of STD acquisition increases with sexual risk behaviors including having unprotected sexual vaginal, oral, or anal intercourse, having multiple sexual partners, having sex with an unfamiliar partner, and having sex under the influence of drugs or alcohol in addition to other risky behaviors like injecting drugs and binge drinking. Clinical and behavioral interventions are therefore crucial in targeting people at risk for STDs by enhancing awareness of STD prevention methods and associated risks. Evidence-based sex education in schools and clinical-based STD screening and risk-reduction programs can play a pivotal role in enabling youth and other high-risk groups to make better informed sexual decisions.

Conclusion

Despite the improvement in STD incidence rates at varying degrees over time, mainly in syphilis and HPV infections, STD infection remains a public health priority for three main reasons:

1. The increase in Chlamydia and gonorrhea rates nationwide.
2. The major health disparity concern due to the disproportional burden on racial and ethnic groups, particularly African Americans; young people and MSM find themselves to be at notably higher risk.
3. The robust association between STDs and HIV acquisition.

Increasing awareness about STD screening and treatment, and providing accessible health services to youth and high-risk groups, is a keystone for meeting the public health priority of STD prevention.

Definition

A suite of emotional, cognitive, and behavioral adaptations designed to prevent a relationship partner from engaging in sex with those outside of the pair-bonded relationship.

Introduction

One of the hallmarks of human (and primate) evolution relates specifically to brain evolution. Humans, compared to other primates, have a highly developed neocortex, which enhances the computational capacity for managing large social networks as well as facilitating self-regulation, both of which contribute to reaping the benefits of cooperating and living in social groups (Dunbar 1998). Nonetheless, humans also evolved bipedalism, and although this has resulted in selective advantages for our species (e.g., grasping, tool and weapon use), it has also generated potential costs as well, specifically the narrowing of the birth canal (Wittman and Wall 2007). Thus, as our brains evolved to be larger, the human birth canal simultaneously became much smaller in circumference relative to other primates. To address the incompatibility of increasing brain size and decreasing birth canal circumference, humans are born with a smaller portion of adult brain size (compared to other primates). Although this aids in the birthing process, it also means that human infants are relatively helpless for an extended period of time post-birth and a significant portion of development in human infants involves brain maturation (Martin 1983). Thus, much of human brain development occurs post-birth with human infants highly dependent upon investment from parents, relative to other primates.

Human infants have benefited from biparental investment (e.g., Quinlan and Quinlan 2007). That is, it has been selectively advantageous in terms of survival and reproduction for infants to receive investment (resources, protection) from both parents, and humans are characteristically more monogamous than many other primates. While biparental investment is advantageous for

offspring survival, infidelity by either partner can undermine these advantages. For example, infidelity by a female partner further undermines men's paternity certainty. Because men do not carry offspring via pregnancy, they never have absolute certainty that offspring birthed by their long-term partner are genetically theirs; sexual infidelity by a female partner exacerbates such paternity uncertainty concerns in men (Platek and Shackelford 2006). Nonetheless, a man's primary partner may be motivated to engage in extra-dyadic sex to produce an offspring with a genetically superior male, thereby increasing the health and survivability of her offspring (Gangestad and Simpson 2000). Additionally, because reproduction is more metabolically costly for women (pregnancy, lactation) than it is for men (the provisioning of a sperm), a female whose partner is unfaithful may experience a reduction in resources invested by the male in her and her offspring (due to resource diversion to females and offspring outside of the pair-bonded relationship; Buss 1988; Trivers 1972). Nonetheless, it can be evolutionarily advantageous for men to mate with numerous females to increase the absolute number of offspring he fathers (Buss and Schmitt 1993).

Although both men and women benefit through mutual investment in shared (genetically) offspring, both may also benefit from engaging in sexual behavior outside of the pair-bonded relationship. One partner's infidelity may be beneficial; the other partner likely incurs costs. As such, men and women have evolved adaptive mechanisms for preventing their partner's infidelity in the first place, detecting potential infidelity by their partner (should it occur) and responding to such infidelity in ways that reduce the reproductive costs associated with it. We summarize research on psychological and behavioral mechanisms for preventing, detecting, and responding to partner infidelity in this entry in terms of men and women's differential responses to that concern as well as burgeoning research on the role of individual differences (e.g., personality) in infidelity prevention behaviors (i.e., behaviors to prevent partner infidelity).

Preventing Infidelity

In the context of preventing infidelity in pair-bonded relationships, Ben Franklin (1735) could not have been more correct, from an evolutionary perspective: “An ounce of prevention is worth a pound of cure.” Human males risk investment in offspring who do not carry their genes if their long-term partner mates outside of the relationship and produces offspring. Although women do not to worry about “maternity uncertainty,” a woman whose partner mates outside of their relationship and produces offspring risks diversion of resources (protection, tangible resources) from her and her offspring. As such, humans have evolved numerous adaptive strategies for preventing infidelity.

Foremost, concern with partner infidelity elicits strong emotional reactions, specifically jealousy. For men, imagined partner sexual infidelity elicits greater anger than for women, whereas the reverse is true for imagined partner emotional infidelity (autonomic nervous system arousal confirms these differences; Buss et al. 1992). These sex differences to potential infidelity are sensible, given that men risk paternity uncertainty and women risk resource diversion. Men and women are highly motivated to enact different strategies to prevent infidelity, which are often referred to as mate retention tactics (Buss 1988). Below, we outline these sex-specific tactics to prevent partner infidelity as well as adaptations that reduce each sex’s propensity to be unfaithful to their partner.

Men’s Strategies to Prevent Female Infidelity

To prevent infidelity by their primary relationship partner, men engage in a variety of behaviors to appear more attractive to their partner as a long-term mate, thus potentially reducing their partner’s interest in extradyadic sex. For example, a common mate retention tactic men report using is benefit provisioning, such as buying gifts for their long-term partner (Buss 1988). Such a strategy is sensible; women’s reproduction is facilitated by

identifying a male partner with access to resources and a willingness to invest those resources in her and her offspring (Trivers 1972). Thus, a man who engages in benefit provisioning is likely to be more attractive as a long-term partner, which could reduce a woman’s motivation to be unfaithful with her current partner. Indeed, research finds that men are much more likely to engage in costly benefit-provisioning behaviors for a long-term partner than for a short-term partner, suggesting that this behavior is designed for infidelity prevention more so than courtship (e.g., Jonason et al. 2009).

Men report utilizing verbal compliments with their partner and sit closer to and act nicely to them as effective strategies. Complimenting and acting nicely toward one’s partner should reinforce the value of the relationship, whereas proximity-enhancing behaviors allow males to monitor and respond to potential mate poachers. Importantly, these strategies appear to be more effective mate retention/infidelity prevention strategies than cost-inflicting strategies, as they could dually communicate benevolence and paternal ability (Buss 1988). Men also use status displays to be attractive to a partner (e.g., Griskevicius et al. 2007), which could ultimately prevent infidelity. Given status’s association with greater access to resources, such displays may make men appear as more attractive long-term mates, thereby reducing their partner’s motivation for extradyadic sex (Buss and Shackelford 1997). Additionally, men increase their use of intrasexual threats (e.g., derogating or intimidating rival males) to reduce the likelihood that such males will try to initiate sex with their partner (Buss and Shackelford 1997).

Men’s infidelity prevention tactics also covary with the probability of partner infidelity and conception risk. For example, men who are concerned with infidelity report engaging in cunnilingus more frequently with their long-term partner for longer durations, which is positively correlated with their partner’s satisfaction with the relationship (Pham and Shackelford 2013a, b). Importantly, men’s cunnilingus provisioning is limited to long-term pair-bonds, suggesting the behavior’s utility in continuing commitment. Men may

use reinforcing sexual behavior to reduce their partner's interest in extradyadic sex (Sela et al. 2015a). Additionally, men's mate retention strategies are correlated with their partner's actual conception risk. Women report that their primary partner engages in more retention behaviors during days of peak fertility (Gangestad et al. 2002; Haselton and Gangestad 2006). Given the link between elevated conception risk and interest in extra-pair copulations (Gangestad et al. 2005), it would be sensible for infidelity prevention strategies to peak when women are most capable of conceiving to prevent extradyadic sex on these critical days.

Along with relationship-controlling and reinforcing behaviors directed toward women, men also display behaviors that reduce their own interest in extradyadic sex. By communicating disinterest in sex outside of the pair-bonded relationship, their primary partner may trust them more and reciprocate that trust via sexual fidelity. For example, men primed with romantic love demonstrate reduced visual attention to attractive female faces. Romantic love evolved to facilitate pair-bonding and biparental investment. By not attending to attractive relationship alternatives, men may be less likely to deviate sexually from their primary partner and, by avoiding their own infidelity, would be more attractive mates (Maner et al. 2008). Additionally, men in relationships, when implicitly primed with mating, demonstrate reduced attention to attractive females compared to single men (Maner et al. 2009; Miller et al. 2012), a potential analog in alternative derogation that would preclude subsequent attraction to alternatives from developing, as attractive individuals are perceived as more likely to be unfaithful (e.g., Thompson et al. 2016). Men also derogate faces of alternative women at peak fertility (Miller and Maner 2010). This derogation also appears more apparent when such alternatives are perceived as more attractive (Plant et al. 2010). By communicating that one is not attracted to females outside of their relationship that are at peak conception risk, men may be more attractive to their primary partner, thereby reducing the likelihood that their partner engages in infidelity.

Women's Strategies to Prevent Male Infidelity

Because paternity uncertainty would be more biologically problematic than resource diversion (in terms of genetic propagation), an asymmetry emerges in preventative strategies based on sex such that men utilize a greater variety of strategies. However, preventative strategies in women remain no less critical in their desire to ensure optimum access to resources. Costs of male partner infidelity include reduced protection, diversion of emotional and tangible resources away from her and her offspring, and potential desertion (e.g., Stieglitz et al. 2012). Women possess their own unique suite of infidelity prevention tactics. For example, to reduce infidelity likelihood, women report acting more affectionately toward their partner, enhancing their physical attractiveness, and using verbal possession displays toward their partners (Buss and Shackelford 1997). Additionally, both women's concern with partner infidelity and desire to maintain their current pair-bond are associated with increased performance of fellatio for longer durations, a behavior used to enhance her partner's attraction to her, rather than other women (Sela et al. 2015a, b). Additionally, women report faking orgasms more frequently when engaging in sex with their primary partner to facilitate their partner's sexual satisfaction (Kaighobadi et al. 2012).

Much like men, women also enact strategies to reduce their own likelihood of infidelity, thereby facilitating their partner's trust in them through such fidelity enhancement cues. Specifically, women visually attend less to attractive opposite-sex relational alternatives when primed with romantic love in a process similar to men (Maner et al. 2008). Partnered women, when primed with mating, also attend less to attractive opposite-sex relationship alternatives, compared to single women (Maner et al. 2009; Miller et al. 2012). Women's awareness of heightened interest in pluralistic mating strategies during peak conception risk also appears to influence their perception of prospective mates. Specifically, women in relationships who are ovulating may recognize the hormonal influence on their current motivational

state as potentially threatening to their current pair-bond, which may lead to greater derogation of potential relationship alternatives. Smith (2015) found that pair-bonded women derogated the attractiveness of male targets who served as alternatives to their current relationship, which would have served to buffer these women from engaging in extradyadic mating. Importantly, these effects were primarily seen among women who reported greater commitment to their current relationship partner.

Mechanisms to Detect Infidelity Cues in Partners and Interlopers

While the most ideal situation for men and women in pair-bonded long-term relationships would be to enact strategies to prevent infidelity altogether, both men and women have conflicting, yet adaptive motives for extradyadic sex. For men, sex with multiple females maximizes his reproductive rate and the absolute number of offspring sired, which increases his genetic lineage (Buss 1988). For women, according to strategic pluralism, extradyadic sex with a more attractive male (associated with good genes) can increase her production of healthy offspring while simultaneously retaining investment by her pair-bonded partner (Gangestad and Simpson 2000). As such, men and women may deviate from pair-bonded relationships, regardless of the infidelity prevention behaviors enacted by their partner. In such circumstances, it behooves men and women to be sensitive to cues in their partners' behavior indicative of potential infidelity or traits in same-sex conspecifics that might indicate an increased mate-poaching threat.

Men's Infidelity Detection Mechanisms

Given the high cost of an unfaithful female partner, men tend to have infidelity detection mechanisms that are oversensitive. That is, men are more likely than are women to overperceive that their partners have been sexually unfaithful. From an error management perspective (Haselton and Nettle 2006), such a bias is sensible.

Overassuming a partner's infidelity is an error (a false alarm), but underassuming infidelity (failing to assume a partner's infidelity when that partner has actually been sexually unfaithful) is a more costly error (a miss) because it increases the likelihood of a male to invest in genetically unrelated offspring (Goetz and Causey 2009). Men use several veridical cues of conspecifics in potentially identifying a partner's infidelity. For example, men tend to attribute greater infidelity risk to women who have highly feminized voices, since feminine voices are associated with youthfulness and attractiveness (O'Connor et al. 2011). Furthermore, men rate highly dominant male faces as even more dominant when their partner is ovulating; given the association of dominance to intrasexual competition and mate value, the presence of dominant male conspecifics might be an especially potent cue of a threat to one's pair-bonded relationship (Burris and Little 2006). Dijkstra and Buunk (2001) further implicate men possessing broader shoulders, an honest indicator of good genes, as evoking perceptions of dominance and subsequent jealousy from rivals.

Women's Infidelity Detection Mechanisms

Although infidelity by a male partner is costly for different reasons, women are nonetheless highly motivated to detect potential infidelity by their partner. Whereas men tend to overassume the likelihood of partner infidelity, women tend to be quite accurate at detecting a variety of infidelity cues. Women tend to attribute greater infidelity risk to men who have more masculine voices, which is sensible, given masculinized men's greater interest in pluralistic mating strategies (O'Connor et al. 2011). In terms of identifying potential rivals, women also utilize visual assessments to determine an individual's threat. Rival women with lower waist-to-hip ratios, a cue to fertility, are perceived as more attractive by men but also more intrasexually threatening by women (Dijkstra and Buunk 2001; Singh 1993). Another multimodal finding corroborates women's upregulation in intrasexual competitiveness

through olfaction. Women who smelled the scent of potential rivals at peak conception risk have heightened levels of testosterone, compared to those who smelled women's scent from luteal phases (Maner and McNulty 2013). This hormonal response may be adaptive to facilitate heightened vigilance against potential rivals. Additionally, women are rather vigilant with respect to rival women and in visual search tasks. That is, women demonstrate enhanced detection of scenarios connoting infidelity (Ein-Dor et al. 2015). These sex-specific acuties would be adaptive to ensure continued provision from a current partner.

Reducing Adaptive Costs of Infidelity

Despite the mechanisms and defenses employed by humans to prevent the occurrence of infidelity in their current relationships, the possibility of infidelity may still pose a threat. Gallup et al. (2005) indicated that 18% of women and 10% of men report having extra-pair copulations during committed relationships, suggesting that infidelity is a genuine threat to pair-bonded relationships. Upon identification, it becomes incumbent to limit costs posed by infidelity. Humans evolved several mechanisms assisting in mitigating costs posed by infidelity. Such techniques differ between men and women. Men's strategies favor frequent and rigorous sexual behaviors to displace potential rivals' sperm in favor of their own (e.g., Gallup et al. 2003). Conversely, women's strategies involve identification of reliable conspecifics who would assist in offsetting loss of resources that a long-term male partner may have typically provided (Miller and Maner 2008). Below, we provide sex-specific responses to genuine concerns of partner infidelity that run the gamut from benefit provisioning (e.g., Goetz et al. 2005) to intimate partner violence and coercion (e.g., Miller and Maner 2008; Goetz and Shackelford 2009).

Men's Mechanisms

Men's behavior in response to infidelity is best understood through the sexual movements to

eliminate potential competitors' sperm. Women can retain sperm from multiple partners with individual sperm having a life span of 5–7 days. Gallup and Burch (2004) posited the most recent male partner having greater chances in insemination. Thus, an adaptive response to double mating could include men's penis shape and behavior evolving to ensure own fertilization while mitigating potential threats posed by rival sperm in the vaginal tract from a previous sexual encounter. The human penis possesses a coronal ridge that operates as a "scooping" tool during copulation by drawing rival sperm from the cervical end of the vagina and replacing it with the current partner's sperm. Such "scooping" results in displacement of approximately 80% of semen already existing in a vaginal tract (Gallup et al. 2003). Successfully displacing sperm would also be contingent on men's ability to utilize their coronal ridge forcefully and attaining sufficient depth in the vagina to reach rival sperm. The required vigorous thrusting during copulation should also be greater, following concerns of infidelity (e.g., Goetz et al. 2005). Furthermore, following ejaculation, men enter a refractory period that precludes their own sperm from becoming displaced that involves loss of an erection and less vigorous thrusting, which would serve as a mechanism to prevent self-displacement (Gallup and Burch 2004; Gallup et al. 2005).

For this mechanical advantage to work, this would require increased copulatory behavior for more rival-displacement opportunities. However, copulatory opportunities may not always be plentiful. A greater degree of uncertainty surrounding potential rivals emerges when time between copulations increases that it would be adaptive for men to engage in sperm-displacing behaviors. For example, Gallup et al. (2003) found that increased time apart from one's sexual partner predicts men's engagement in more vigorous thrusting behavior to compensate for the possibility of double mating. Such displacement behaviors are also more apparent when infidelity risk appears higher (e.g., attractive partner; Goetz et al. 2005). Along with the actual sexual behavior corresponding to displacement, other behaviors emerge to facilitate eventual copulation. Greater time apart since the most recent copulation

predicts men's greater interest in sex with a long-term partner and perception of one's partner as more attractive (Shackelford et al. 2002, 2007). Further, rejection from a partner also elicits greater distress and persistence from men to eventually having sex, primarily if their partner has many male friends (Pham and Shackelford 2013c; Shackelford et al. 2007). Pham et al. (2017) further indicate that greater numbers of a wife's male friends and coworkers lead husbands to greater frequency of copulation.

Given the link between frequent in-pair copulations and mate guarding (Shackelford et al. 2006), infidelity risk also elicits more male mate-guarding strategies. Men at greater risk of mate guarding are more willing to engage in cunnilingus until their partner achieves orgasm (Pham et al. 2013b). Goetz et al. (2005) indicate that men experiencing greater infidelity risk engage in more mate-guarding behavior. Specifically, men utilize benefit-provisioning (e.g., love and care) and possessive strategies (e.g., verbal possession) more frequently as a function of competition risk. Benefit provisions and mate guarding also appear especially high when the woman is perceived as possessing a higher mate value (e.g., Pham et al. 2014; Starratt and Shackelford 2012). Starratt et al. (2007) have also found that men who perceive greater intrasexual competition have greater propensity to monopolize their partner's time to prevent contact with potential rivals and more aggression toward other rivals (Miller and Maner 2008; Starratt et al. 2007). The threat of cuckoldry predicts men's proclivity not only to coax women into sex but also predicts actual use of sexual coercion themselves (Camilleri and Quinsey 2009; Goetz and Shackelford 2009). Camilleri and Quinsey (2009) have also found that many rapists' concern over cuckoldry was a driving factor behind their crimes. These concerns have similarly been theorized as the basis of violence directed toward one's partner (for a review, see Kaighobadi et al. 2009). The increased spousal abuse in response to cuckoldry fears could be adaptive in potentially deterring women from considering infidelity in the future. For example, anxiety and accusations of infidelity predict partner-directed violence aggression (Armocky et al. 2015b; Kaighobadi et al. 2012).

Women's Mechanisms

Because women have complete certainty regarding the maternity of their offspring, their concerns following knowledge of their partner's infidelity are not centered around expending resources on another's child. Instead, given the investment often required of men in long-term relationships (Trivers 1972), learning of a partner's extra-pair relations appears to redirect women's desire for affiliation to those who are better able to provide for them. Women are more likely to incur greater costs from a single act of intercourse that puts them in a position to desire more resources. Miller and Maner (2008) found that women are more interested in seeking reaffiliation with others if they believe their partner to be unfaithful. While this desire for conspecifics should readily satisfy affiliative needs, access to more conspecifics would also ensure greater contact with potential resources that would offset the costs incurred from partner infidelity in women's committed long-term relationships.

Individual Differences in Infidelity Prevention

Given the within-species diversity exemplified by humans, individual differences in infidelity detection and mate retention behavior seem inevitable. For example, humans demonstrate varying levels of proclivity toward pluralistic mating strategies, with their successful utilization of pluralism being contingent on one's exhibition of good genes that would make them desirable mates. Those who do not exhibit good genes or those who may not adopt pluralistic mating strategy should thus be more averse to the thought of infidelity and may be more likely to perform more aggressive maintenance behaviors compared to those who may perceive themselves as having more mating opportunities. This section outlines both individual differences in physical appearance and personality in how either classification of traits influence responses to potential infidelity in an adaptive manner.

Physical Differences

Individual differences pertaining to phenotypic expression should leave some individuals more vulnerable to infidelity from a partner. Those who exhibit better genetic quality would likely feel more secure about their current pair-bond and thus not have to engage in aggressive mate-guarding or cost-inflicting behavior as frequently as those who may perceive themselves as not possessing commensurate fitness indicators in their own right. In fact, previous findings indicate high-mate value men engage in more benefit-provisioning tactics compared to lower-mate value men (Miner et al. 2009), particularly those whose partners have a perceived higher mate value (Sela et al. 2016).

Another desirable physical trait for men to possess is height (Stulp and Barrett 2014). Height is highly heritable trait that may also assist in benefit provisioning (e.g., Macgregor et al. 2006), which may suggest that taller men in committed pair-bonds may feel greater relationship satisfaction, as their height may serve as a buffer against their partner's interest in extra-pair copulations with taller individuals. Indeed, Brewer and Riley (2009) found that taller men report greater overall satisfaction with their relationships and ultimately report less jealousy toward prospective intrasexual rivals. These findings further suggest that those who exhibit objectively lower genetic quality compared to intrasexual rivals, however, should report greater jealousy in their relationships. Indeed, previous research indicates that individuals demonstrating worse overall fitness (e.g., health issues, fluctuating asymmetry) report greater concern of partner infidelity and ultimately greater jealousy within the context of their current relationship (Arnocky et al. 2015a; Brown and Moore 2003). Taken together, an individual who perceives to be of lower genetic quality would benefit from engaging in behaviors to affirm the established pair-bond, whereas those of higher quality may feel more afforded in not having to be vigilant of their partner or having to aggress against potential competition.

Personality and Infidelity Prevention Strategies

Personality appears to exert similar influence over infidelity prevention strategies. Individuals exhibiting higher levels of ostensibly prosocial traits are more willing to provision partners, whereas those low in such traits may demonstrate more aggressive mate-guarding behavior to continue established pair-bonds. When considering the HEXACO model, high-conscientiousness, high-agreeableness, and high-openness individuals are less likely to mate guard in their current relationship, whereas high-emotionality individuals appear more willing to mate guard (Holden et al. 2014). Importantly, individuals who are low in honesty-humility are more willing to manipulate and exploit their partners. Pham et al. (2016) have also found that low-honesty and low-conscientiousness individuals utilize coalitional mate guarding as a prevention strategy or the covert use of conspecifics to monitor one's relationship partner on behalf of that individual. Using the Big Five traits, de Miguel and Buss (2011) found greater vigilance toward partner's potential indiscretion as a function of neuroticism. Among more negative traits, Holden et al. (2015) have also found that pathological personality traits (as indexed by DSM-5 criteria) are associated with greater use of cost-inflicting mate-guarding strategies. In terms of attachment styles, men with an avoidant attachment are less willing to utilize benefit-provisioning infidelity prevention strategies compared to securely attached men (Barbaro et al. 2016).

In terms of benefit provisions, personality traits also correspond to various compensatory behaviors that seek to enhance one's partner. For example, individuals who score high in trait conscientiousness report greater use of resource displays (i.e., behavior indicating beneficence for the partner) as well as greater levels of appearance enhancement (de Miguel and Buss 2011). Importantly, these researchers also found that agreeableness predicted a reduction in cost-inflicting strategies, including punishment and derogation of one's mate. Individuals with an anxious attachment style are also more likely to engage in benefit

provisioning with a romantic partner (Barbaro et al. 2016). In terms of sexual behaviors employed to retain a partner, research has also found various personality traits correlate with proclivity to engage in oral sex. For example, Sela and colleagues (2015c) found that women's trait level of openness predicts their interest in performing fellatio in a long-term relationship while their conscientiousness predicts the duration of performing such an act. Similar findings have emerged for men such that agreeableness and conscientiousness predict their engagement in cunnilingus (Pham et al. 2015).

Conclusion

Given the heavy investment in child-rearing, it is crucial for humans to possess mechanisms to mitigate the likelihood of the dissolutions of necessary pair-bonds for offspring survival. Thus, humans appeared to have evolved various psychological and behavioral adaptations that would serve not only to facilitate individuals' identification of potential infidelity risks vis-à-vis their partner but also to encourage their own continuation of that pair-bond. Such adaptations manifest in several capacities ranging from benign gift-giving to coercion with various environmental and dispositional factors influencing preventative responses. This entry addressed several posited means of infidelity prevention.

Prey Availability

Mark A. Krause and Lyra Skopos
Southern Oregon University, Ashland, OR, USA

Synonyms

[Resource availability](#); [Resource selection](#)

Definition

Prey availability refers to the quantity and diversity of food items available to a predator.

Introduction

Prey availability determines what predators eat, and predators in turn influence prey availability. Considerable complexity underlies this axiomatic statement. Numerous ecological and evolutionary processes influence fluctuations in the relative abundance, and therefore availability, of prey. For example, life history factors, mortality, fecundity, disease, migration, and resources influence whether a species of prey is available to eat. Conversely, predators play a direct role in prey availability because their presence and activity may result in changes in prey population numbers.

Prey Availability and Foraging Decisions

Prey availability affects foraging behavior at both short- and long-term scales. It influences immediate decisions about what to eat and where, and it can also impact behavioral development and evolution. With regard to the former, prey availability may decline for an individual or group of foragers when a food patch becomes depleted or prey have taken evasive action. The prey choice model of optimal foraging theory predicts that a forager should pursue a particular prey item if the energy gained from consuming it exceeds that of an alternative type of prey. In the classical prey model, prey is chosen as a function of energy value divided by handling time (capture and consumption). The rate of intake is affected by this relationship as well as by predatory encounter rates with prey. For example, wolves prefer elk as their primary prey over bison. This is likely because elk are comparatively easier to capture and subdue than bison, providing a greater relative net energy gain. However, when elk populations decline, wolves will prey upon bison instead (Garrott et al. 2007).

Prey availability applies to models of foraging in patchy environments. The marginal value theorem predicts that organisms monitor depletion of

a given patch and balance current caloric availability with requirements to locate a new, replenished patch (Charnov 1976). Simply put, if prey become scarce in a predator's current foraging location, the predator will need to move to a new one. For example, organisms may alter their food and patch choices in accordance with seasonal changes. Biomass and abundance of fish in the Sylt-Rømø Bight vary throughout the year, with maximum values of each occurring during summer and minimums during winter. Harbor seals preferably feed on benthivorous fish in the summer when they become more available in the Sylt-Rømø Bight. During winter and fall, the seals switch their foraging location to the North Sea, where there is a greater abundance of benthivorous prey relative to the Sylt-Rømø Bight. However, seals in both the Sylt-Rømø Bight and the North Sea feed mainly on pelagic fish species in the spring when benthivorous species are smaller and less abundant (Vega et al. 2016). Changes in harbor seal foraging locations, and seasonal changes in diet, serve to increase energy efficiency across a spatiotemporal scale.

The loss or depletion of a particular food source in a patch may simply require that the predator alter its diet rather than search for prey in a new location. The generalist snake species *Thamnophis elegans* feeds opportunistically on metamorphic amphibians and fish inhabiting Eagle Lake in Lassen National Forest, CA. A 7-year period of lake recession saw plummeting amphibian populations, resulting in the near elimination of amphibians from snake diets (Kephart and Arnold 1982). Although fish were sufficiently available prior to and during the change in water level, the snakes prioritized toads because they offered a higher energy return owing to their lower capture cost in comparison to fish. Such ontogenetic shifts in prey choice in response to availability are not unusual among generalist feeders.

Prey Availability, Plasticity, and Evolution

Prey availability is an important ecological force influencing both ontogenetic and evolutionary processes. Food resource partitioning among

conspecifics in regions of sympatry may result in changes in behavior and trophic morphology that are mediated by phenotypic plasticity. Outcomes of food resource partitioning include increased foraging efficiency among conspecifics specializing on different available prey and, possibly, evolutionary divergence reinforced by assortative mating or further partitioning of habitat use. Indeed, competition for food is a primary mechanism of evolutionary divergence (West-Eberhard 1989).

Arctic charr (*Salvelinus alpinus*) are known to specialize on either benthic (macroinvertebrate) or pelagic (plankton) prey. These fish show high levels of phenotypic plasticity of trophic morphology, and different feeding experiences induce shape and size variation of the body and head. In the laboratory, captive born and reared Arctic charr with robust head and mouth morphology foraged for benthic prey, while charr with slender body and head shape fed on pelagic prey (Garduño-Paz and Adams 2010). Natural variation in head size and shape and correlated differences in diet have also been observed in wild-caught charr in regions of sympatry. These findings indicate that prey that are simultaneously available and abundant are not consumed equally by a natural predator. Resource partitioning among conspecifics, such as found in Arctic charr, can result in important microevolutionary changes (Skúlason and Smith 1995).

Further evidence for diet-induced microevolutionary change comes from studies of geographic variation in resource availability, morphology, and behavior (Foster and Endler 1999). Animals that consume different available food resources undergo both developmental and microevolutionary changes to adapt to local feeding conditions. Such locally adaptive responses, maintained by geographic isolation, play a major role in reinforcing reproductive isolation and, ultimately, speciation. For example, this pattern has been observed in coral feeding butterflyfish (*Chaetodon* spp.). Several different species of butterflyfish occur along coral reefs in the South Pacific Ocean. Three of these species are generalists, taking a relatively wide range of prey including soft and hard coral as well as motile invertebrates, and two are specialists, feeding

only on hard corals (Lawton and Pratchett 2012). It is important to note that prey availability is one of many factors influencing both micro- and macroevolutionary change, as is the case with butterflyfish. However, prey availability and dietary habits are of clear evolutionary importance, as they are related to species diversification. Phytophagous insects tend to be highly specialized on specific species of host plants, possibly as a strategy for responding to diverse mechanisms of defense employed by plants. In this case dietary specialism is favored. Indeed, among phytophagous insects, and probably other taxa, the evolutionary trend is to evolve from a dietary generalist into a specialist (Nosil 2002).

Predator-Prey Dynamics and Prey Availability

Intraspecific and interspecific interactions between predators are influenced by the availability as well as the behavior of prey. Male mountain lions (*Puma concolor*) in central California mainly feed in riparian woodlands where mule deer (*Odocoileus hemionus*) are abundant. Females, however, often feed closer to human-populated areas in order to avoid confrontations with males. Intraspecific aggression over prey carcasses, which can result in males attacking females and their offspring, may be the driving force behind this resource partitioning. Female mountain lions may feed in different locations in order to increase the safety of their young, despite the risks this brings via their encroachment on developed areas (Benson et al. 2016).

Curiously, when heterospecific predators hunt the same prey, the effort required to acquire that prey may be reduced for each predator when they both occupy the same patch. For example, the presence of horned vipers (*Cerastes cerastes*) facilitates barn owl (*Tyto alba*) predation on gerbils by forcing the prey into open areas where owls can more easily catch them. Conversely, when owls become an immediate danger to the gerbils, the latter will shift to a bush microhabitat where vipers prefer to hunt (Embar et al. 2014).

The dynamics that exist between predator and prey present a challenge to estimating prey

availability. Specifically, the activity patterns of prey species, and responses of prey to the presence of predators, influence estimates of prey availability conducted by researchers (and rates of prey capture by predators). For example, in the presence of various species of predatory shorebirds, fiddler crabs (*Uca* spp.) flee into their burrows to evade capture. Hiding in burrows reduces the amount of time crabs can engage in evolutionarily important behaviors such as courtship and foraging. Therefore, there are costs to either strategy – either the crabs miss out on opportunities to mate and eat because they are hiding or they increase their risk of being eaten because they are not (Backwell et al. 1998). Here, from the perspective of the prey species, availability is a function of how the animals respond to the evolutionary trade-offs they face.

Prey Availability and Human Foraging

A comparative framework for studying the effects of prey availability on human foraging is challenging because animal domestication and agriculture have fundamentally changed how humans acquire, store, and utilize their food. The most germane comparison comes from contemporary human groups that rely on hunting, gathering, and fishing for subsistence. Slobodkin's "prudent predator" hypothesis emphasized examples of predators focusing on younger or older prey rather than those in reproductive prime. This hypothesis fits with ideals we might hold for how humans hunt and forage, as we hope that our species has the intuitive foresight to avoid overharvesting in order to remain in harmonious equilibrium with prey. However, observations of the Mascho Piro people of Peru, an indigenous tribe of hunter-gatherers, do not suggest that this particular group adjusts its foraging tactics to maximize long-term prey availability (Alvard 1995).

In fact, large-scale work examining global impacts of hunting and fishing further raises doubt that humans are *sustainable exploiters*. Rather, from a comparative perspective, humans exploit prey populations at levels far outstripping

nonhuman predators, particularly large terrestrial carnivores and fishes (Darimont et al. 2015). Thus, reduced prey availability tends not to result in reduced consumption (e.g., conservation), and population sizes of large carnivores and fish are mitigated by constantly high kill rates, particularly of animals at their reproductive prime. These observations, however, do not mean that people who obtain their food through hunting and gathering are entirely free from the constraints of prey availability. Seasonal changes in prey activity, abundance, migratory patterns, and other factors are sources of variation in prey availability with which contemporary hunter-gatherers must cope (Bliege Bird and Bird 2005).

Conclusion

Prey availability is a constant constraint to which predators must respond in order to survive. Immediate foraging decisions involve weighing the costs and benefits associated with prey availability, as shown in models of optimal foraging. Even when organisms have adapted to particular, energy-maximizing diets available in their given environments, changes in the quantity and quality of preferred food items may lead to changes in prey choice, patch choice, and predatory tactics. Thus, on a long-term scale, prey availability is an ecological force affecting selection for successful foraging tactics. Phenotypic plasticity of behavioral and trophic morphology in response to dietary variation can in turn influence macroevolutionary events (speciation). It should be noted that prey availability is not a simple index of how much breeding has occurred in a given prey species. Rather, the activity patterns of prey and their responses to the presence of predators are two of many possible influences on how much prey is actually available to predators.

Prey Choice

Mark A. Krause and Lyra Skopos
Southern Oregon University, Ashland, OR, USA

Synonyms

Foraging decision; Prey preference; Prey selection

Definition

The term *prey* refers to an organism or part of an organism (e.g., eggs, seeds) that is consumed by a predator. *Prey choice* refers to the outcome of an organism's decision to seek, capture, and consume a specific type of prey. This may encompass a choice between alternative and available prey species, or opting for a specific characteristic of one particular prey species, such as a polymorphic variant or optimally sized prey item.

Introduction

In order to survive, and ultimately reproduce, animals must consume enough calories to meet their energetic requirements. Foraging involves balancing the benefits of consuming prey items that satisfy the energetic requirements of the predator with the costs and risks involved in finding and handling prey. Choice, therefore, plays an important role in predator behavior. Take, for example, crows foraging for clams along an intertidal zone. The crows actively search for and dig up clams of various sizes (and therefore caloric value). A crow then flies to a rocky surface where the clam can be dropped and broken and its contents made accessible. Large clams may require several flight-drop bouts before they break. The time and energy involved in searching for a large clam and possibly having to drop it multiple times are costs to the predator. The benefit (calories gained) of taking a single, large clam should

exceed that of taking multiple smaller clams. Thus, crows must make a choice about what size of clam they should seek out, and what size they should reject, in order to maximize net energy gain that is balanced against foraging costs. Being too finicky and ignoring small clams come at a cost, as does spending excess time trying to break large clams. Richardson and Verbeek (1986) measured the relationship between foraging effort and clam size in crows and estimated that the threshold for the optimal size clam is 28.5 mm. Thus, the *optimal decision rule* for a crow foraging for clams is to select one that is at least 28.5 mm and then expend the energy required to fly to a suitable location to break it open and consume it. As this classic example illustrates, there are trade-offs that determine what animals choose to eat.

Time and energy are key currencies influencing prey choice, but animals must also weigh other variables. For example, foraging may increase an animal's susceptibility to predation. A forager may need to leave a nesting area and therefore increase the vulnerability of its offspring. Furthermore, the quality, availability, and behavior of potential prey species influence prey choice. Choice of clam size by crows involves a decision rule encompassing variation of a single prey species. Predators may also follow decision rules that involve switching among alternative prey species. Canadian lynx (*Lynx canadensis*) shows a preference for snowshoe hare (*Lepus americanus*), but when population numbers of this prey decline, they opt for more abundant rodents (Stenseth et al. 1997). The switch from hare to rodents is an obligatory one, as it is attributable to declining availability of their preferred prey. Predators also actively seek ideal prey among several alternatives (Shulz and Finlayson 2010). Ecologists and animal behaviorists have long sought to model the complex dynamics between predators and their prey and, in doing so, predict and explain prey choice.

Modeling Prey Choice

Classic papers by Emlen (1966), MacArthur and Pianka (1966), and Schoener (1971) marked a

major surge of interest in modeling animal foraging behavior. Common elements across approaches to modeling animal feeding strategies include a currency that is maximized (calories), a cost-benefit function (e.g., reducing search time), and a solution toward an optimum (choosing the most profitable prey). Optimality modeling was integral to behavioral ecology through the 1990s, and although its popularity has waned, it continues to be a valuable approach to studying and understanding prey choice.

One useful concept is the *optimal diet model*, also referred to as the prey choice or contingency model, which predicts that animals should select the most profitable prey available (Krebs and Davies 1993). Larger prey may be more profitable because they afford greater net energy gain relative to smaller prey. However, subduing, transporting, and processing large prey require increased energy expenditure by predators. According to the optimal diet model, the ratio of energy gain (E) relative to handling time (h) determines the profitability of a prey item. Optimal foraging theory predicts that large prey will be chosen over small prey such that:

$$\frac{E_1}{h_1} > \frac{E_2}{h_2}$$

where E_1 is the energy value of the large prey item and h_1 is its handling time and E_2 is the energy value of the small prey item and h_2 its handling time. Based on this simple equation, the predator should choose to consume the larger prey₁ whenever it is encountered. What should the predator do if prey₂ is encountered? Prey₂ may be more profitable if the energy gain from eating it is greater than the gain from spending time (and energy) searching for larger prey₁ (see ► [Search Time](#) for further discussion on how this is modeled).

Work with numerous predator-prey systems supports the optimal diet model. Classic work by Elner and Hughes (1978) demonstrates optimal diet selection by shore crabs (*Carcinus maenas*) feeding on mussels (*Mytilus edulis*). Crabs position mussels using both major and minor chelae and then apply crushing force with the major chela to break open the shell and access the flesh. When

given unlimited access to mussels of different sizes, shore crabs choose the optimally sized ones (e.g., ones that are readily breakable and yield high calories). Crabs deviate from optimally sized prey if resources become depleted. Subsequent work showed that the presence of conspecific competition hastens the handling time of mussels and so actually increases the rate of energy intake (Chakravarti and Cotton 2014). Reduced handling time may be due to more rapid and forceful shell breakage, which results in quicker access to prey, but also carries increased risk of claw damage. Optimal diet selection is therefore influenced by the presence of conspecifics. Further examination of the optimal diet model suggests that it does well to account for prey choice in species that consume immobile prey but less so in predator-prey situations that involve active pursuit and capture (Sih and Christensen 2001).

Optimal foraging theory presumes that food is evenly dispersed, which may or may not be realistic. Food resources may exist in patches, with abundant resources in some areas and no food in other areas spanning a predator's home range. As a patch of food becomes depleted, the net energy gain from remaining at that patch drops below optimal and the organism may choose to locate a new patch. Charnov's (1976) *marginal value theorem* predicts that organisms will move to a new patch when net energy gain at the current one drops below gains that could be acquired by switching locations. Studies manipulating patch quality in laboratory simulations or seminatural situations suggest that the marginal value theorem accurately describes and predicts some aspects of foraging behavior (Lima 1984).

The marginal value theorem models individual foraging decisions, but group foraging presents an additional challenge. The decision to move to a different food patch may be influenced by the number of conspecifics currently utilizing a particular patch. Three-spined sticklebacks (*Gasterosteus aculeatus*) will congregate in foraging groups that are in proportion to food availability: When large quantities of food are at a patch, a large group of fish will forage at that location, and when small quantities are available,

a small group will forage at that location (Milinski 1979). Sticklebacks and other group foragers thus conform to the *ideal free distribution model*, which predicts that group size at a given patch of food will be in direct proportion to the amount of food at that patch.

Learning Processes

Laboratory-based operant learning paradigms have been used to study choice and foraging behavior in animals (Fantino and Abarca 1985). A general procedure for this type of work involves arranging concurrent schedules of reinforcement, where two schedules are simultaneously presented and free-operant responding by the subject (key pecking or lever pressing) to each schedule is monitored. For example, if a concurrent schedule is arranged such that one key is on a fixed ratio 3 (FR3) schedule, and the other is on an FR10 schedule, the organism should choose the FR3 schedule because the payoff is always better. Responding three times instead of ten times is always more efficient and profitable. However, concurrent schedules can be configured to more accurately represent the types of decisions that foraging animals must make. In nature food does not become available with the predictable regularity of an FR schedule. A concurrent schedule using variable ratios models how responding (e.g., searching for prey) is sometimes rewarded after many attempts or after very few attempts (Williams and Fantino 1994).

Furthermore, predators encounter prey that appear at different time intervals. Concurrent schedules of reinforcement using fixed-interval (FI) schedules model this facet of animal foraging (Fantino and Abarca 1985). For example, an FI-20s schedule and a FI-40s schedule give the subject the option of food reward after 20 s and 40 s have elapsed since the last response, respectively. The schedules are in effect regardless of whether the subject is responding, so the optimal choice is to respond to both keys. Of course, key presses will occur more frequently to the FI-20s schedule than to the FI-40s schedule, but the organism obtains the best payoff when it allocates its responses to each schedule.

The allocation of responses on concurrent reinforcement schedules tends to follow a pattern described by the *matching law*, which states that the relative rate of responding to alternative reinforcement schedules is directly proportional to (matches) the amount of reinforcement available for each (Herrnstein 1961). The matching law is expressed as:

$$\frac{BA}{BA + BA} = \frac{rA}{rA + rB}$$

where B represents behavior, such as a key peck, r is the rate of reinforcement, and A and B refer to the levers or keys that can be operated on two different schedules.

The use of concurrent reinforcement schedules and applications of the matching law has furthered our understanding of how animals make choices about feeding in the laboratory, and may apply to natural situations, though their ecological validity is questionable. Also, this approach is heavily focused on the process of choosing between alternatives of the same type of food. While this indeed does occur in nature, it does not directly address why or how organisms switch to different types of available prey.

Applications to Human Evolutionary Psychology

Studies of prey choice and modeling of foraging behavior have focused primarily on nonhuman species. Applying general principles of foraging behavior to humans is challenging because our species has harnessed considerable control over the food that is available for consumption: For most societies, agriculture and animal domestication obviate the need to actively hunt and gather for sustenance. There remain some exceptions comprising human populations that acquire food through hunting and gathering or subsistence foraging. These populations likely express how human populations foraged prior to agriculture and animal domestication.

An illustrative example comes from the Ache tribe of Eastern Paraguay. At the time of Hill

et al.'s (1987) observations, the Ache spent about a quarter of their days foraging in forested areas near the agricultural settlement they had inhabited since the 1970s. During these bouts of foraging the Ache hunt for animals such as peccaries, coatis, and capuchin monkeys and gather fruits, honey, and insects. Behavioral recordings and measures of returns on foraging bouts showed that optimal Ache hunting and gathering habits were dictated by the encounter rates and return rates of available food sources. Consistent with optimal foraging predictions, such as the optimal diet model, Ache foragers utilized food resources that offered significant returns in caloric value relative to efforts required to obtain them. This is why small prey such as insects, small fruits, and small birds were sometimes ignored so that foragers could pursue larger rewards such as peccaries. Furthermore, they did not exploit resources that would reduce returns from foraging bouts.

Based strictly on net caloric gain, foraging for and consuming plant matter is more profitable than hunted game. However, the protein provided by meat is highly valuable to the health status of humans, and optimal health is predicted to result in higher reproductive rates. Additionally, animal products are indispensable due to their lipid content, believed to be the most important nutritive component of animal tissue. This also justifies the pursuit of larger game as it provides a larger reserve of food with higher nutritional value to compensate for the fact that different hunting or gathering parties may acquire food at varying time periods and of different energy returns. As such, the models of optimal foraging theory in the context of the Ache must be modified to recognize the intrinsic health value of available food substances. There is also the matter of optimizing the time spent practicing different foraging strategies. Because there are so many different nutrients to be optimized, the Ache must recognize when the exploitation of one food source must be abandoned in place of another. Ultimately, any food type will have diminishing returns if over-exploited, reducing that food's caloric and nutritional payoff. Also, certain food sources, such as

armadillos, were only pursued during seasons in which they are large enough to be worth the effort (Hill et al. 1987).

Evolution, Plasticity, and Prey Choice

Prey choice has multiple determinants involving evolutionary, ecological, and behavioral factors. Evolved sensory capacities, such as search images or olfactory sensitivity, cue predators toward what type(s) of prey to pursue. Prey switching occurs when the relative abundance of potential prey species changes. Encounter rates between predator and prey will change due to a variety of factors, such as fluctuations in relative population numbers, migration, and defensive and evasive responses by prey. Ecological models predict that prey switching (or frequency-dependent predation) occurs in direct proportion to the abundance of a prey species, with high attack rates associated with elevated prey abundance and low attack rates with low abundance (van Leeuwen et al. 2013).

Evolutionary and ecological processes are major influences on predator-prey responses and dynamics. For example, predators that have evolved a resistance to the defensive mechanisms employed by potential prey offer compelling examples of the relationship between natural selection and prey choice. Garter snakes (*Thamnophis sirtalis*) consume a variety of amphibian species but express an aversion to newts (*Taricha granulosa*) that secrete a noxious chemical (tetrodotoxin) on their skin surface. Both species have a broad geographic distribution across North America, with regional “hotspots” where they share extensive habitat overlap. Garter snake populations inhabiting these hotspots have evolved a resistance to the toxicity of the newts and even incorporate them into their normal diet (Brodie et al. 2002). Thus, prey choice is controlled by both proximate factors such as abundance, migration, and learning, as well as ultimate factors involving evolutionary change. The predator-prey “arms-race” between garter snakes and newts nicely illustrates the relationship between natural selection and diet.

Prey choice is also influenced by rapid ecological disturbances. Bushmeat hunting in Congo basin rainforests influences prey choice by leopards. Cats inhabiting regions with high levels of bushmeat hunting feed on relatively small, less-desired prey in comparison to leopards that do not face such competition (Henschel et al. 2011). Species introductions into wild habitats can also influence both prey choice and avoidance. Cane toads (*Bufo marinus*) are lethally toxic to predators and were introduced in Australia in 1935. Populations of black snakes (*Pseudechis porphyriacus*) that have historical geographic overlap with cane toads actively avoid them when tested in the laboratory and instead choose to eat native frogs. Toad-naïve black snakes readily attempt to eat the toxic toads when tested in the laboratory. Laboratory experiments also show that aversion to toads is not the result of individual learning but rather to an evolved genetic disposition to avoid toads that has emerged over only about 23 generations among populations with historical overlap with cane toads (Phillips and Shine 2006).

Snakes are an ideal model for studying the mechanisms and evolution of prey choice. Snakes consume more than 2000 different species of prey, and what they eat is determined by jaw and body size, phylogenetic constraints, predatory tactics (e.g., envenomation or constriction), geographic distribution, and habitat (Burghardt 1993). The underlying genetic and experiential components of prey choice in snakes can be understood by examining geographical variation of a single species (Krause and Burghardt 2007) or by studying interspecific variation among species showing both shared and uniquely derived dietary preferences (Waters and Burghardt 2013). The genus *Thamnophis* includes several species with diverse, geographically variable diets. Neonatal common garter snakes (*Thamnophis sirtalis*) show chemoreceptive sensitivity to different prey species commonly consumed by adult snakes. Prior to their first feeding experience, neonates direct tongue flicking and predatory strikes toward chemical cues of species-typical prey (Burghardt 1993). While relatively strong responses are directed toward species-typical prey, feeding experience modifies chemoreceptive

responses and also prey choice. Predatory experience with a variety of prey species modifies the search, capture, and ingestion efficiency by garter snakes (Burghardt and Krause 1999; Krause and Burghardt 2001). Plasticity of predatory behavior is particularly important for a dietary generalist such as *T. sirtalis*, with neonates born into geographic locales with variable prey availability. Prey choice for garter snakes, and many other species with widespread geographic distributions, is largely determined (and constrained) by the populations into which they are born.

Genetic factors also interact with feeding experience to influence sensory responses and prey preference. Neonatal garter snakes born to mothers collected from a population that feeds almost exclusively on earthworms show strong and roughly equal chemoreceptive responses to both fish and worm chemical extracts prior to feeding experience (Burghardt et al. 2000). The heritability of these initial responses to both prey species is zero. However, after 12 feedings on fish, the relative change in chemosensory responding to fish (but not worm) odor was significant ($h^2 = 0.53$, $p < 0.0005$). Also, in simultaneous prey choice tests, the snakes showed significant, heritable ($h^2 = 0.26$, $p = 0.05$) preferences for fish over worms. These results demonstrate that genetic processes underlying prey choice change with predator experience. Also, prey choice is facilitated by ecological circumstances. Garter snakes are thought to have evolved from ancestral species that consumed mostly fish and amphibians, but not worms (Rossman et al. 1996). The snakes studied in Burghardt et al. (2000) showed a strong latent response and preference for fish, despite the worm-based diet consumed in natural conditions.

Prey choice in snakes and other organisms is influenced by intraspecific and intersexual morphological variation. Head size and mouth shape and size show considerable phenotypic variation in many vertebrate and invertebrate species, which may arise through evolutionary or epigenetic processes. Arctic charr (*Salvelinus alpinus*) reared on different diets of either large or small prey developed differently sized heads and mouthparts after 24 weeks of feeding experience (Adams et al. 2003). In wild situations, this type of feeding-induced plasticity could result in foraging

specializations and therefore differences in prey choice, within a single species. The foraging specializations in charr and other species could in turn reinforce differences in trophic morphology (Adams et al. 2003). Relatedly, female-biased size dimorphism of body and relative head size, present at parturition through adulthood, has been found in various snake species, including garter snakes (Krause et al. 2003). Among some species, female snakes have larger heads (adjusting for body size) than do male snakes, which may facilitate reduced resource competition between the sexes (Houston and Shine 1993). Wild-caught adult garter snakes show both intersexual and ontogenetic, diet-induced variation in body and head size. Adult females have larger heads than males, regardless of diet, and females from a geographic locale that feeds upon large-bodied vertebrates are significantly larger than are females that feed primarily on earthworms (Krause et al. 2003; Krause and Burghardt 2007). Such differences reflect both intersexual and intraspecific evolutionary and ecologically based dietary divergence, and they can further reinforce differences in prey choice.

Conclusion

Numerous variables influence prey choice. Optimal foraging models capture generalities such as relationships among profitability, handling, and search time: Predators alter their feeding behavior to maximize caloric profitability and minimize energy and time expenditure and predation risk to themselves and offspring. Decades of work in the field of behavioral ecology has shown the utility of optimality models in explaining and predicting prey choice. Agriculture and livestock production impose barriers to applying optimal foraging models to human prey choice, although some work on traditional hunter-gatherer groups has revealed some important insights. In addition to the variables modeled in optimal foraging theory, prey choice is determined by several proximate and ultimate factors. Prey availability certainly influences what predators choose to eat. Predators may switch to new prey via passive mechanisms, such as when a prey species

becomes more or less abundant. Or, a new species of prey may be incorporated into a predator's diet, which is especially likely among predatory generalists such as common garter snakes. Genetic, experiential, and epigenetic processes are also involved in alterations in prey choice. Feeding experience can influence the growth of body and trophic morphology, which can in turn reinforce ontogenetic changes and intraspecific differences in prey choice.

Definition

Parts of the auditory cerebral cortex.

Introduction

The auditory cortex involves a complex organization of connections between cells in order to process auditory information (Moller 2013). Based on an elaborate network of intrinsic and extrinsic connections, the auditory cortex is responsible for the conscious perception of sound and provides the foundation for the comprehension and production of meaningful sounds (Hackett 2015). Moreover, the auditory cortex is defined by the areas of the cerebral cortex that receive thalamic input from one or more divisions of the Medial Geniculate Complex (MGC) (Hackett 2011). The complete anatomy of the human auditory cortex is not completely known, and there is no common consensus amongst investigators regarding the names of the human auditory cortices. Furthermore, the exact anatomic location of the auditory components of the auditory cortex in humans varies from one person to another (Moller 2013). The primary and the secondary are briefly discussed next.

The Primary Auditory Cortex

The **primary auditory cortex (PAC)** occupies the cortex of the supratemporal plane (STP) and is bordered by auditory association areas in circular sulcus and superior temporal gyrus (STG) (Pandya 1995). Further evidence using structural MRI suggests that the location of the PAC is on a region on the medial two thirds of Heschl's gyrus corresponding to Brodmann's area 41 (Pickles 2012; Wasserthal et al. 2014; Moller 2013).

Creating a tonotopic mapping of the auditory cortex has been proven to be a challenging process. This is due to the small size of the auditory cortical fields relative to the spatial resolution of neuroimaging techniques, and the lack of a common consensus in regards to the specific architecture of the human auditory cortex

in terms of its areal borders and number of subdivisions (see Saenz and Langers 2014). Up to date, the only acoustic parameters that have been found to be topographically mapped are frequency (Isaa et al. 2017; Wolak et al. 2017) as well as other complementary maps such as modulation rate (Lithari and Weisz 2017), sensory tuning bandwidth (see Saenz and Langers 2014; Wang and Eliades 2017), and sound intensity (see Bilecen et al. 2002).

The Secondary Auditory Cortex

While neurons from the primary auditory cortex respond mainly to sound, some neurons in the area of the **secondary auditory cortex** respond to other somatosensory stimuli such as touch and vision (Moller 2013). Recent research has indeed shown a structural connectivity between visual cortex and auditory cortex (Chen et al. 2013) as well as multimodal sensory interactions between the sensory cortices (see Hosokawa et al. 2017). According to Moller (2013, p.103), the secondary cortex areas have specific roles such as connecting different parts of the brain. It is noteworthy that both primary and secondary auditory cortices take up only a small fraction of the neocortex. The largest part of the neocortex is composed of association cortices (see Moller 2013, p.103).

Conclusion

The anatomy and function of the primary and secondary auditory cortex was briefly discussed. There have been efforts to create a tonotopic mapping of the auditory cortex. However, the only acoustic parameters that have been successfully mapped are frequency, modulation rate, sensory tuning bandwidth, and sound intensity.

Definition

One individual acting to benefit another individual. This includes mutualistic cooperation where two or more individuals act together to provide benefit for all.

Introduction

Cooperation is widespread and an integral part of primate life. Most primate species live in social groups providing many opportunities for cooperation, and this is reflected in the variety of cooperative behaviors observed such as grooming, alarm calls, and coalitionary support that pervade primate life. These behaviors vary in several aspects including how costly they are to individuals carrying them out, the benefits to the recipients, how many individuals are involved, and how frequently they occur. The following section will describe the main forms of primate cooperation and discuss proposed ultimate and proximate mechanisms involved in these behaviors.

Diversity of Primate Cooperation

By far the most common form of cooperation in primates is allogrooming. Individuals spend a large amount of time (up to 20 %) meticulously cleaning the fur and skin of others (Dunbar 1991), in doing so reducing their own vigilance and spending time that could be used for other activities. The time spent on this activity suggests that it has an important function. Part of this is likely hygienic, e.g., by removing parasites, but the major function is social. Grooming is an important aspect of establishing and maintaining social relationships (bonds); pairs that spend more time grooming each other are also more likely to cooperate in other contexts.

One of the correlates of grooming is coalitionary support. As well as cooperating, group members compete for resources, either directly or indirectly via positions in the hierarchy. This can lead to direct aggression between individuals; others may join in on either side of the fight, risking injury to themselves. Social bonds, measured by grooming or proximity, then influence who joins the fight in support of whom.

Food sharing is a further form of cooperation between individuals. Usually this refers to tolerated theft where one individual allows another to take some food from them, though there are also some cases of active transfer where food is given

to another. Food sharing is most common between adults and young, but in several species sharing also occurs between adults. In some cases this is between males and females, possibly related to mating opportunities, such as savannah baboons or rhesus macaques sharing with females on consortships. In other cases sharing can also be between same-sex partners: male chimpanzees will share meat, a highly valuable resource, after a hunt with both male and female group members (Jaeggi and Gurven 2013).

The examples of primate cooperation described thus far are cooperation on a dyadic or triadic level, but cooperation can also involve one individual helping many more individuals or several individuals working together. Alarm calls provide valuable information about a potential threat (including what type of predator) while possibly making the caller more vulnerable to the threat (by drawing attention to themselves). Evidence of audience effects, where individuals are more likely to call when others are present than when they are alone, indicates that this information is for other group members, and recent field experiments with chimpanzees have suggested that they also adjust calls according to whether recipients already know of the danger or not (Crockford et al. 2012).

In contrast to alarm calling, where one individual provides a benefit to many other group members, predator defense and intergroup conflict are two contexts in which several group members may act together in a way that benefits all group members. When neighboring groups of wild capuchin monkeys (*Cebus capucinus*) encounter each other, it can also result in aggression between the groups. Not all group members are involved in these encounters; rather some individuals will leave, presumably to avoid potential danger. Playback experiments have shown that the likelihood of individuals avoiding the intergroup conflict increases with the number of group members present (Crofoot and Gilby 2012). So we see that primates can be cooperative but not indiscriminately so; in some cases, they avoid cooperating to their own benefit.

Grooming, alarm calling, and territory defense are characteristic of primates living in groups.

However, there are also some forms of cooperation that are specific to only a small number of species. Two interesting examples are cooperative hunting and cooperative breeding. Hunting in groups is only seen in chimpanzees (and to a lesser extent in white-faced capuchins). Evidence from some chimpanzee populations suggests that group hunting is cooperative as hunts are more likely to be successful with increasing numbers of participants. The hunter that catches the prey (usually a colobus monkey) keeps possession of it, but will allow others to take pieces. This way a significant proportion of the group will benefit in some way from the hunt. Current research aims to identify whether and how hunters coordinate their actions with each other and how this may vary across populations.

Cooperative breeding is seen in callitrichids (tamarins and marmosets). In some species not only do fathers contribute to the care and provisioning of the infants but also nonparent helpers (often but not always previous offspring). This breeding system is of particular interest because it involves high levels of cooperation and the mature helpers generally do not breed while they are helpers, paying a seemingly high cost to fulfill their role (Digby et al. 2006). This brings us to the ultimate and proximate mechanisms of cooperation in primates.

Mechanisms of Primate Cooperation

The evolutionary puzzle of cooperation stems from the idea that during cooperation individuals are increasing the fitness of others while reducing their own. Therefore, the ultimate mechanisms of cooperation must explain how these behaviors evolved. The proximate mechanisms then aim to explain behavior on the individual level such as the motivational, cognitive, and physiological factors involved.

One important ultimate factor in primate cooperation is inclusive fitness or kin selection. This is particularly apparent in matrilineal species like vervet monkeys, macaques, and baboons; most cooperation (e.g., grooming and coalitionary support) occurs between members of the same matriline (Silk 2007). The proximate mechanisms that lead to preferential may not necessarily

involve individuals recognizing relatives (though there is some evidence that this may occur). Preferences for kin can also be achieved through contextual cues such as familiarity: by spending time with their mother individuals will be more familiar with their maternal siblings as well as other maternal relations such as aunts. Additionally, if there is male reproductive skew, in other words if the alpha male sires most offspring during his tenure, then a preference for same age peers will result in a preference for paternal siblings (Widdig 2007).

Cooperation also occurs regularly between unrelated individuals. In some cases cooperation is mutualistic: all parties benefit and there is no “evolutionary puzzle” to solve. An example may be cooperative hunting by chimpanzees as with increasing number of hunters, the likelihood of a successful hunt increases. While mutualistic cooperation is less of a puzzle from a theoretical perspective, the proximate challenges of coordinating behaviors remain. Experiments with captive populations have found great apes are able to coordinate their behavior for mutual gains by waiting for a partner when they need one (Melis et al. 2006).

When cooperation between unrelated individuals is not mutualistic, one individual pays a cost to benefit another. In this case the evolutionary assumption is that these benefits are reciprocated in some way (reciprocal altruism). There are several different accounts as to how this occurs differing in the time scales of reciprocation, the currencies exchanged. Long-term field observations show that grooming is reciprocated over medium to long time frames, but not short time frames. This is consistent with experimental studies that find little evidence for contingent reciprocity, suggesting that primates are not necessarily keeping track of each individual exchange (Amici et al. 2014). Rather, much cooperation is part of long-term stable relationships, termed social bonds or friendships (Silk 2007). These can be between kin and non-kin and within or between sexes (depending on the social structure of the species) and are characterized by spending more time in proximity, grooming more, and being more likely to support one another during aggressive interactions. The emotional bookkeeping

account proposes that these interactions result in an emotional response to another individual which then determines the quality of the relationship and the likelihood of further cooperation (Schino and Aureli 2010). This theory does not account for all instances of cooperation, but it does highlight that social bonds are a key aspect of primate life.

Conclusion

The examples of cooperation above are not exhaustive, but they should make it clear that primate cooperation is widespread and multifaceted; cooperation is integral to primate life. However, the examples should also make clear that cooperation is not separate from competition: the two are closely intertwined, and being able to cooperate with others is a part of successfully competing with group members. In summary, the variation in primate cooperation both within and between species reflects the complexity of primate social lives.

Definition

In nonhuman primates, dominance hierarchies represent one dimension of group social organization. The dominance hierarchy is a clearly discernible ranking order of group individuals, determined by the outcomes of aggressive and submissive (together, agonistic) social interactions that create asymmetrical dominance relationships between individuals.

Introduction

Nonhuman primates exhibit a wide range of social systems, from solitary living to large groups whose composition is fluid and changing;

however, the majority of species show a clear tendency to live in relatively stable, cohesive groups (Isbell and Young 2002). Indeed, numerous diverse animal species have evolved to live in groups, including hyenas, elephants, badgers, elephant seals, and sheep, among many others. A key feature of social organization that has repeatedly evolved in such group-living species is the dominance hierarchy (Lea et al. 2014; Sterck et al. 1997). Dominance hierarchies are an emergent property of asymmetrical agonistic (aggressive and submissive) interactions among group members in which some individuals consistently defeat others, leading to a discernible ranking order (Klass and Cords 2015). These agonistic interactions can take place in a variety of contexts, including access to important limited resources such as food, mates, high-quality habitat, or affiliative partners (Lea et al. 2014). An individual's dominance rank can thus be an important social variable that influences individual behavior and life history.

Describing and Quantifying Dominance Hierarchies

Researchers have developed a wide range of quantitative and descriptive measures to evaluate and compare primate dominance hierarchies. Some measures are indices which describe properties of the dominance hierarchy as a whole, and some refer to characteristics of individuals or subgroups within the hierarchy. Some of the main measures used to quantify dominance hierarchies in primates are described here.

Two widely used summary indices are linearity and steepness. Dominance hierarchies are often measured in terms of their *linearity*, i.e., the degree to which the rank order is transitive (de Vries 1995). In a completely transitive dominance hierarchy, there are no circular dominance relationships, in which, for example, A is dominant to B, B is dominant to C, and C is dominant to A. Rather, the rank order is entirely linear; in a group of six individuals, the top-ranked animal outranks five others, the second-ranked animal outranks four others, and so on. In a completely

nonlinear dominance hierarchy, all individuals will dominate the same number of group mates, and the dominance hierarchy will resemble a web, as opposed to a straight line. While *steepness* also describes the dominance hierarchy as a whole, unlike linearity this index quantifies the power differentials between adjacently ranked individuals, i.e., how certain dominant individuals are to win in interactions with subordinates (de Vries et al. 2006). The higher the steepness of a hierarchy is, the more asymmetrical the relationships within the group, and the more unlikely it is that subordinate individuals would win in agonistic encounters with individuals that are dominant. An additional aspect of the dominance hierarchy that is useful for descriptive and comparative purposes is *rank stability*, which refers to how stable (i.e., constant) the rank order is over time (Bergstrom and Fedigan 2010). Hierarchies in which individual animals frequently change position, moving up or down in rank, are less stable. Stable, and therefore predictable, dominance relationships and rank orders may be beneficial in that they may potentially reduce the risk, stress, and energy inherent in aggressive interactions (Perlman et al. 2016).

Dominance hierarchies are also characterized in terms of the *rates of aggressive or submissive behaviors*, or rates of agonistic interactions overall, experienced by different individuals within the group. Dominance hierarchies often differ in the frequency of agonistic interactions among individuals, and variation may also be seen between high-ranking and low-ranking individuals, who can display marked differences in the rates and types of interactions they experience and whether they display primarily aggressive or submissive behaviors (Klass and Cords 2015). The *severity of aggressive behavior* may also vary, from simply displacing a subordinate individual in space to threatening vocalizations and facial expressions and up to high-intensity physical attacks such as hitting or biting (Lu et al. 2008; Thierry et al. 2007).

An additional important aspect of a dominance hierarchy is the determinants of *rank acquisition*.

There are two main types: in one, dominance rank is determined largely by an individual's competitive ability, stemming, for example, from age, strength, or body size. In the second type of dominance hierarchy, rank is largely "inherited," meaning individuals acquire ranks similar to those of their close kin, which often result from relatives supporting each other in agonistic encounters with nonrelated individuals (Lea et al. 2014).

Three descriptive dimensions are commonly used to describe and differentiate among dominance hierarchies in primates, and the values of many of the above measures are considered indicative of these different types of dominance hierarchies (Isbell and Young 2002; Sterck et al. 1997). The *egalitarian-despotic* dimension describes how clearly established and formalized the dominance hierarchy is, with despotic hierarchies being highly linear and steep with clearly asymmetrical dominance relationships between dominant and subordinate individuals, whereas egalitarian hierarchies are nonlinear, shallow, and harder to detect. Despotic dominance hierarchies may also vary in terms of the *tolerant-intolerant* dimension, which describes how tolerant dominant individuals are of subordinate individuals. Tolerant hierarchies are characterized by decreased severity of aggression from dominants and an increase in challenges from subordinates, leading to overall more symmetrical dominance relationships and less steep dominance hierarchies. Conversely, intolerant hierarchies will display higher intensity aggression in agonistic interactions and highly asymmetrical interactions, as well as less frequent postconflict reconciliation and affiliative behavior. Lastly, the *nepotistic-individualistic* dimension describes the main determinants of rank order; in highly nepotistic dominance hierarchies individuals acquire ranks similar to their kin, and whole kin groups can be ranked relative to one another, whereas in individualistic hierarchies kin rank independently of one another and rank is determined by characteristics of the individual (Klass and Cords 2015; Thierry 2007).

Dominance Hierarchies in Primates: Variation and Phylogenetic Patterns

Primate groups differ in many ways. In terms of dominance hierarchies, two important types of variation that may shape the existence and type of hierarchy that develops are (Isbell and Young 2002):

- (i) Size of the basic social unit. Dominance hierarchies are not an important aspect of social organization in species that are largely solitary or pair-bonded; those that form stable groups can range in size from only a few individuals to hundreds (e.g., mandrills; Setchell and Wickings 2005).
- (ii) Group composition, i.e., single-male/multi-female, single-female/multi-male, or multi-male/multi-female. In species characterized by single-male groups, the dominance hierarchy describes relationships among the females only (and vice versa), whereas in multi-male/multi-female groups, all adults of one sex are usually dominant over the other (e.g., the more rare female dominance in ring-tailed lemurs; Koyama et al. 2005), and the dominance hierarchies of males and females are often analyzed separately, and may be quite different in terms of characteristics such as stability or determinants of rank.

Group composition is shaped by patterns of dispersal, the departure of juveniles or adults from their natal group (the group in which they were born) or current reproductive group to find and settle in a new group in which they attempt to reproduce (Lawson Handley and Perrin 2007). In many primates, dispersal is sex-biased, with mainly or only one sex dispersing and the other remaining in the natal group; the latter is termed the philopatric sex. Most Old World cercopithecines and many strepsirrhines display male dispersal and female philopatry, while this pattern is less common among apes and New World platyrrhines, which tend to have female-

biased dispersal (Lawson Handley and Perrin 2007; Printes and Strier 1999). Exceptions to these general phylogenetic patterns are however quite common, and in some species both sexes disperse at similar rates. A small number of species are characterized by the much rarer strict male philopatry, including chimpanzees, bonobos, spider monkeys, and marmosets (Silk 2009).

Dispersal patterns shape the type and longevity of relationships within the group, including dominance relationships. For example, in female-philopatric species where males disperse, females are able to form nepotistic dominance hierarchies that are stable over generations, where kin support each other in agonistic encounters and rank close together, as they remain in the same group with their female kin throughout their lives (e.g., yellow baboons; Silk et al. 1999).

Initial studies of female primate dominance hierarchies largely focused on a number of cercopithecines, a subfamily of Old World monkeys, many of which are terrestrial, living in open habitats that allow for easy observation. In these well-studied, female-philopatric taxa, such as Japanese and rhesus macaques, chacma baboons, and vervet monkeys, females display similarly stable, despotic, and nepotistic dominance hierarchies. However, while this type of dominance hierarchy has been shown to be quite common and indeed phylogenetically conserved among female-philopatric Old World monkeys (Di Fiore and Rendall 1994), subsequent studies of additional taxa from all primate radiations have uncovered a broad, diverse range of dominance hierarchies among female primates.

For example, the 22 species in the genus *Macaca* largely share the same basic group structure (multi-male/multi-female) and dispersal patterns (most males disperse to new groups at least once in their lifetime, and females are philopatric, permanently remaining in their natal group), leading to females with largely stable, nepotistic dominance rankings and males with dominance status that varies throughout their lifetimes. However, the dominance hierarchies of females in different macaque species vary

considerably in terms of despotism and tolerance, based on differences in the asymmetry in dominance relationships, severity and frequency of aggression, stability of dominance hierarchies, and numerous other attributes (Thierry 2007). Indeed, considerable variation in agonistic behavior and dominance hierarchies has been documented across populations of the same species (e.g., patas monkeys; Isbell and Pruettz 1998), and among groups within a single population (e.g., blue monkeys; Klass and Cords 2015).

The variation in female primate dominance hierarchies only increases when one looks beyond the cercopithecines. Female-philopatric, forest-dwelling Hanuman langurs have stable, linear dominance hierarchies in which rank correlates with physical condition (Koenig 2000). Female mountain gorillas have female dispersal and stable dominance relationships in their nonnatal groups, where rank is determined by age and group tenure (Robbins et al. 2005), and female chimpanzees disperse from their natal groups and have infrequent agonistic interactions and non-linear hierarchies (Pusey et al. 1997). Among female platyrrhines and lemurs, while some exceptions display dominance hierarchies that are similar to the above “typical cercopithecine” hierarchy (e.g., capuchins; Bergstrom and Fedigan 2010), rates of agonism are extremely low compared to cercopithecines (Wheeler et al. 2013) and clear dominance hierarchies are often difficult to detect (e.g., black howler monkeys; Van Belle et al. 2011).

Male primate dominance hierarchies have not been studied to the same extent as female dominance hierarchies (see “[Explaining the Evolution of Primate Dominance Hierarchies: Socioecological Models](#),” below), in terms of variation within and between species, and characterization of despotism, tolerance and nepotism, and their attendant numerical measures. However, several insights are available from existing research.

Linear hierarchies have been documented in many species with multi-male/multi-female groups where all males disperse from their natal groups to seek reproductive opportunities elsewhere, such as ring-tailed lemurs, olive baboons, mandrills, Nepal gray langurs, and crested black

macaques; by contrast, male white-faced capuchin dominance hierarchies have a clear alpha male but do not display a linear hierarchy among the rest of the group males (Perlman et al. 2016). In such species, adult male dominance rank is often determined by the shifting competitive abilities of each individual and the males he is competing against (Perlman et al. 2016; Thierry 2007). These types of male dominance hierarchies are thus often determined by individual attributes, such as fighting ability, size, or strength, which are often correlated with age, leading to an inverted U-shaped correlation curve between rank and age, with males achieving their highest ranks in their prime (Perlman et al. 2016).

In chimpanzees, a male-philopatric species, males compete aggressively for access to females and display linear dominance hierarchies (Muller 2002). They often also cooperate in agonistic coalitions to challenge rivals or maintain exclusive access to females, and agonism with fellow group males is often (but not always) less severe than that displayed in between-group encounters. In at least some populations, male chimpanzees show much higher rates of aggressive behavior, and more intense aggression, than female chimpanzees, and more dominant males show higher rates of aggressive behavior (Muller 2002). Chimpanzee social relationships have been compared to those of female baboons, although nepotism does not play as large a role in structuring relationships in male chimpanzees (Silk 2009). Much less is known about dominance hierarchies among male-philopatric New World species, such as marmosets and spider monkeys, although aggression between male spider monkeys is rare (Slater et al. 2009), male marmosets are known to maintain egalitarian dominance relationships, and males of both species show a considerable degree of affiliative and cooperative behavior (Silk 2009).

Explaining the Evolution of Primate Dominance Hierarchies: Socioecological Models

In some primates, a high dominance rank has been shown to provide fitness-related benefits such as

lower stress levels, reduced risk of aggression, or preferential access to food or mates, and ultimately, higher reproductive success, for both males and females (Majolo et al. 2012). While in studies of individual groups or populations this positive correlation between dominance rank and fitness benefits is not always apparent, a recent meta-analysis showed that broadly speaking, dominant males have significantly higher mating success and significantly higher fecundity (Majolo et al. 2012). A pattern of significantly higher female fecundity in some species, particularly in species with longer lifespans and significantly higher proportion of infants surviving, was also shown.

However, dominance hierarchies are important not only in terms of their consequences for the life history and fitness of individuals within the group but also for our understanding of social evolution: Why do dominance hierarchies form? Why are they such a ubiquitous feature of group living? What causes the enormous amount of variability seen in dominance hierarchies both across and within primate species? A number of ecological and social factors are considered to be the main variables that explain the evolution and variation in primate dominance hierarchies, and these have been combined in several socioecological models (Sterck et al. 1997).

The original socioecological model, developed by Wrangham (1980), focused on the effects of feeding behavior and competition on the formation of primate groups. Wrangham's (1980) model addressed only the "typical" diurnal cercopithecine primate group, with a core of related, philopatric females with a clearly discernible, stable dominance hierarchy, and is based on the fundamental hypothesis that females compete primarily for environmental resources, while males compete primarily for access to females.

This model was then modified by van Schaik (1989) to incorporate the effects of predation avoidance. In van Schaik's socioecological model, female primates form groups primarily as a mechanism of predation avoidance, owing to improved predator detection,

reduced per capita capture risk, and the potential for communal defense. Group living then leads to feeding competition among females, both within and between groups. The type and intensity of feeding competition is determined by the distribution, type, and abundance of food sources relative to group size, and this competition then shapes female social relationships, including agonistic interactions (which often occur in the context of feeding) and dominance hierarchies, similarly to Wrangham's (1980) original model. The distribution of males is then determined by the distribution of females.

van Schaik's (1989) model was further expanded by Sterck et al. (1997) to incorporate the effects of interactions between males and females on group structure and social behavior, specifically the effects of infanticide by males. Sterck et al. (1997) and subsequent studies (e.g., Isbell and Young 2002; Lu et al. 2008) also further developed model predictions regarding the specific effects of different types of feeding competition on agonistic relationships and the formation of dominance hierarchies among female primates, thereby expanding the applicability of the socioecological model to species that display dominance hierarchies that differ from the despotic, nepotistic hierarchy seen in many female-philopatric cercopithecines (e.g., spider monkeys; Slater et al. 2009). When individuals experience strong within-group resource competition, agonism should be frequent, leading to linear, steep, nepotistic, and stable dominance hierarchies, where kin support each other in agonistic encounters against nonkin. However, if competition over food resources occurs mainly between rather than within groups, females should benefit from forming group-wide alliances, which may lead to the formation of more egalitarian and tolerant dominance hierarchies that are less steep. When both types of resource competition are important, they may interact to produce clear dominance relationships and stable, linear, nepotistic hierarchies with a relatively high level of tolerance. Infanticide risk should also increase tolerance, similarly to competition between groups, because females benefit from defensive coalitions with

other group members against aggressive males. Thus when infanticide risk is high, shallower hierarchies with lower intensity aggression should be seen.

While many of the predictions of socio-ecological models are often and consistently borne out in studies of wild primates (see Isbell and Young 2002; Klass and Cords 2015; Sterck et al. 1997), a wide consensus has yet to be reached on the causes leading to the formation of primate dominance hierarchies and the considerable variation seen across and within species (Klass and Cords 2015). With their focus on proximate ecological and social factors, these models predict variation in social organization and behavior independent of any potential constraining effect of phylogeny (Isbell and Young 2002), and thus may only be able to provide partial explanations to observed patterns of dominance hierarchies across species (Clutton-Brock and Janson 2012; Klass and Cords 2015; Thierry 2007).

Conclusion

Dominance hierarchies are an important component of social behavior and organization among group-living primates. Primates display an impressive array of dominance hierarchies that differ in many ways, including between males and females of the same species. The evolution of this variety in dominance hierarchies is the result of a complex interplay of ecological, demographic, social, and phylogenetic variables, and while much remains to be discovered regarding the evolution of this aspect of social behavior among primates, it is clear that evolutionary history, resource competition, predation, dispersal patterns, infanticide, and group size all likely play important roles in shaping agonistic behavior and dominance hierarchies. Dominance hierarchies in turn shape individual primates' experiences within groups and their access to important resources, which may ultimately translate into differential effects on overall fitness and reproductive success.

Definition

Visual signals displayed behaviorally by members of the Primate order, which include lemurs, galagos, bushbabies, tarsiers, Old World monkeys, New World monkeys, great apes, and humans; manual gestures are visual signals displayed by the arms and hands.

Introduction

The most populous primate species, humans, displays rich gestural repertoires. Some human gestures seem universal, whereas many are culturally specific. For example, begging gestures are understood the world over, but the vertical extension of the index and middle fingers in a “V” configuration can mean “peace” (USA) or, depending on its

orientation to the recipient, either “victory” (UK, palm towards recipient) or an obscene expletive (UK, palm oriented away from the recipient). Long considered subsidiary to speech, human gestures have increasingly been characterized as a component in a language system that is inherently multimodal, displayed in multiple sensory channels. With this theoretical accretion of gesture into theories of the evolutionary origins of language has come a concomitant interest in the manual gestures of our nearest living relatives, the great apes.

Primate Gestures

Initial catalogues of primates’ communicative behaviors emphasized facial expressions, vocalizations, and whole-body postures. The first systematic description of apes’ manual gestures was by van Lawick-Goodall (1968), for chimpanzees at the Gombe Stream National Forest, in Tanzania. Fieldworkers subsequently applied functional analyses of apes’ gestural behavior, reporting language-like properties of manual gestures by chimpanzees, based on the theoretical framework of Bates et al. (1975). According to this view, human children begin life in an expressive mode (perlocutionary) and then develop an intentional mode of nonverbal communication (illocutionary) in which gestures and other signals are used to particular ends, culminating in the onset of speech (locutionary) near the end of the first year of life. This framework has been applied to the repertoires of chimpanzees at Gombe Stream; to free-ranging orangutans at the Tanjung Puting Reserve, in central Indonesia; and to numerous analyses of gestural communication in captive ape colonies. According to this framework, whereas locutionary communication is uniquely human, both perlocutionary (expressive signals not under volitional control) and illocutionary signals (intentional communication) are displayed by great apes and monkeys.

Apes display, both in the wild and in captivity, a number of different illocutionary signals. These include, primarily, proto-imperative gestures (requests, commands), for example, requests to be picked up, play solicits, and begging gestures. They also display what Bates and her colleagues

called proto-declarative gestures – the use of objects or the self to capture and manipulate the attention of an observer. Proto-declaratives include a number of overt displays, such as leaf-clipping, in which leaves are abruptly and ostensibly clipped by the signaller’s teeth, and running away with an object. In captivity, there are numerous examples of language-trained apes pointing declaratively, although at the time of this writing, this is disputed by a number of researchers who believe that proto-declarative communication is unique to the human species, that proto-declarative signaling signifies attempts to manipulate the mental states of the recipients of proto-declarative signals, which implies that the signaller has some ability to discern invisible psychological processes in others.

Intentional Communication

For many philosophers, to claim intentionality in the communication of an organism is to claim that the signaller represents the mental state of a recipient of a signal. This influential psychological process model entails that some mental state, an intent, in the signaller is encoded in communicative behavior, and then the original intent is reconstructed through an inferential process in the receiver. Recently, this model has been criticized on grounds that such claims are unverifiable. Most contemporary work in this area applies objective behavioral criteria developed in the study of human communicative development; thus, human babies are said to communicate intentionally when they use gestures to manipulate the behavior of their older caregivers in goal-directed sequences of behavior (Bates et al. 1975). Human babies after about a year of age are understood to communicate intentionally when they accommodate their gestural signals to the visual focus of an observer, alternate their gaze between an observer and the entity to which they are pointing, and they work to repair breakdowns in communication, by repeating their signals or elaborating upon them, when misunderstood (Leavens et al. 2005). All of these characteristics of intentional communication have been

documented in the great apes (chimpanzees, orangutans, gorillas, and bonobos), and subsequent work has demonstrated at least some of these characteristics of intentionality in the gestural communication of some monkey species. Chimpanzees and capuchin monkeys have even been reported to withhold pointing gestures and to point deceptively when a human experimenter establishes a pattern of taking food away when its location is indicated by the animal. At present, the state of the empirical evidence is that monkeys and apes communicate intentionally with gestures, where intentionality has been operationalized to conform with the objective behavioral criteria that establish the development of intentional communication in young humans. The metaphysical question as to whether intentional communication implicates mental state attribution remains open.

Relevance to the Origins of Language

Primate gestures are relevant to a number of contemporary theoretical debates. With respect to theories of the origins of language, scientists look to the manifest intentionality of gestures, which are directed to particular individuals, as evidence that the capacity for human speech was based on an evolutionary platform of intentional communication by gestures in our prehuman forebears (Arbib 2005; Corballis 2002). Subsequent work on captive ape populations established that apes choose the modality of signaling to accommodate the visual orientation of the recipients of their gestures, using audible signals to capture attention and visual signals (like gestures) when recipients are visually attending to the signallers – this implies that apes are sensitive to the behavioral markers of attentiveness in the recipients of their signals. Recent work with both Old World and New World monkeys demonstrates similar kinds of sensitivity to receiver status in the display of manual gestures. Thus, sensitivity to the attentional status of an observer when deploying manual gestures has been reported in Anthroidea (apes and monkeys).

The majority of humans are right handed (left-hemisphere dominant) for gesturing, and this asymmetry has been taken to support a theoretical model in which the left hemisphere dominance for speech was evolutionarily built on an existing left hemisphere specialization for manual gestures (Arbib 2005; Corballis 2002). Studies of handedness in primates reveal a right-hand population bias for manual gestures in great apes and some monkeys (Hopkins et al. 2012). Moreover, in accordance with Dunbar's (e.g., 1996) hypothesis that the origins of language lie in affiliative vocalizations that functionally replace manual grooming, it has been found that chimpanzees are primarily right handed for grooming, which constitutes a mode of tactile communication between individuals. These findings, collectively, are consistent with the idea of an anthropoid left-hemisphere cerebral bias for intentional communication with manual gestures.

Gesture Development and Social Cognition

Another contemporary theoretical debate to which primate gestures are relevant concerns the development of gestures. While many human gestures are conventional (e.g., the V-sign discussed above), some human gestures have been considered to be universal, such as begging and pointing. Among nonhuman primates, most researchers agree that some gestures seem to be biologically based and universal in some species. Examples include begging – which is displayed by the great apes and humans with an outstretched arm and a cupped, supinated palm – and species-specific gestures like the chest-beating display of male gorillas. Tomasello and his colleagues later developed the hypothesis of *ontogenetic ritualization*, the idea that intention movements, which represent whole actions, come to stand for the whole action within any given pair of individuals (e.g., Call and Tomasello 2007). An example of ontogenetic ritualization: when mothers offer their babies objects and the children reach for them, eventually, the children later use their reaching behaviors to instrumentally request object

delivery from their mothers. Chimpanzee juveniles, for example, develop a “tickle-me-here” gesture, involving the placement of their fingertips against the backs of their own necks, and another gesture involving presentation of the ventrum towards the interactive partner; this develops after experiences of being tickled in these spots by the caregiver. Thus, idiosyncratic gestures were taken to imply that individual pairs of primates conventionalize and abbreviate their gestural signaling through repeated interactions. Byrne and his colleagues (e.g., Genty et al. 2009) have criticized this interpretation of the development of ape gestures on several grounds, including (a) that rare gestures were misinterpreted as idiosyncratic based on too few observations, (b) that with large troops typical of wild apes, there becomes an upper limit to the available time to ritualize gesture meanings between all possible pairs of individuals, and (c) there are some gestures that clearly cannot be abbreviated – they give the example of drumming against a tree. On these grounds, they argue that the default hypothesis should be that ape gestures are mostly species typical and genetically canalized. Bard et al. (2014) recently examined the development of some chimpanzee gestures and found evidence for a multitude of developmental processes, including genetic canalization (gestures of submission), ontogenetic ritualization (tickling requests), and a dual-directional dyadic process that they term the “co-construction of meaning” in which both individuals actively construct conventional understandings of signals (grooming solicits).

Pointing and Other Nonverbal Deictic Signals

Finally, there is a contemporary concern with deictic gesturing among primates (use of gestures to indicate specific entities, e.g., pointing, Leavens et al. 2005). Long considered unique to humans, pointing and other such deictic gestures have now been demonstrated in representatives of the three genera of great apes, including orangutans, gorillas, chimpanzees, and bonobos, and

several monkey species, including rhesus macaques, capuchin monkeys, Japanese macaques, and baboons. Human pointing was previously viewed as depending on uniquely human and advanced cognitive capacities to refer to specific entities, and pointing by non-human primates poses a challenge to this erstwhile theoretical consensus. There are three theoretical responses to the emerging findings on primate pointing. In what we might term the Promethean perspective, pointing is viewed as cognitively complex when humans do it, but pointing by other animals is viewed as the consequence of simpler psychological mechanisms. In the Dionysian view, pointing by nonhuman primates heralds the same capacity for representing others’ mental states as it allegedly does when humans do it. Finally, in the socioecological view, pointing is seen as a relatively simple, problem-solving tactic that is adopted by humans and other primates when they are prevented from directly accessing desirable entities; pointing becomes a tool for the manipulation of others when barriers (e.g., cage mesh) prevent direct access to one’s environment. Pointing is frequent in captive populations of apes, but very rare in wild ape populations, although it does happen occasionally in wild habitats. Neither the Promethean nor the Dionysian views on pointing clearly predict this paucity of pointing in the wild, whereas the socioecological perspective predicts this pattern, based on the assumption that captivity imposes a problem space on captive apes that is not often encountered in the wild.

Conclusion

Primate gestures are used intentionally by a range of primate species, although clear evidence of the psychological mechanisms at play continues to elude us. Anthropoid primates use gestures to wide variety of ends; to solicit play, tickling, grooming; to request food and other items; to specify an entity of joint interest; to express subordination and dominance; to solicit sex; and to reposition sexual partners. Within different species, some gestures seem to be

genetically canalized, whereas others may be more conventionalized. There seems to be a right-hand bias for primate gestures, implicating a left-hemisphere specialization for intentional communication. Taken together, these findings support the idea that the common ancestor of humans and nonhuman primates had some of the cognitive bases on which humans later developed speech.

Primate Menopause

Margaret L. Walker

Neurology, Emory University, Atlanta, GA, USA

Synonyms

[Great apes](#); [Humans](#); [Monkeys](#); [Reproductive aging](#)

Definition

The permanent, non-pathologic, age-associated cessation of ovulation.

Introduction

Menopause is fundamentally a physiological process, and the eventual cessation of female reproductive capacity is common to many primate species. Our understanding of this phenomenon is hindered by a paucity of data, especially in wild animals, and the differences that occur in wild versus captive animals that may obscure the full understanding of this physiological phenomenon.

Menopause is not a uniquely human life event; ample evidence suggests that this biological event occurs in a number of species, including non-human primates. Much of the confusion about the cessation of reproductive viability in non-human primates arises from the difficulty in confirming this phenomenon. Data arise from a variety of sources – field work, captive primate colonies, and from postmortem analyses of reproductive tissue. Evolutionary biologists take a different approach than do endocrinologists and reproductive physiologists, and these disparate

approaches often muddy the waters. Inferring reproductive senescence and postulating menopause based on data from the last live birth, a common approach in field biology and anthropology, provide interesting but inconclusive data. Evaluation of hormonal and histological data in aging nonhuman primates reveals a more compelling picture. It is clear that different methodological approaches to the issue of primate menopause can lead to vastly dissimilar conclusions (Walker and Herndon 2008; Alberts et al. 2013).

Definitional issues of menopause are problematic. Is it simply the “permanent cessation of menstruation” (Oxford English Dictionary 2006) or, more importantly from a biological perspective, the “cessation of ovarian steroid hormone secretion” (Johnson et al. 2004)? Perhaps the most appropriate approach is to view menses as a tangential marker and to focus on underlying physiology which more accurately reflects aging in the hypothalamic-hypophyseal-ovarian axis. Primate menopause, therefore, requires one to expand beyond the notion of menstrual bleeding to include follicular depletion, absence of perineal swelling (in some species), and hormonal changes indicative of permanent anovulation. Understanding of primate menopause can perhaps be more easily achieved if one understands that reproductive aging is not a singular event but rather a process. Falling birth rates, follicular depletion, and increased anovulatory cycles signal a system in decline.

In human females, where menopause occurs relatively early in life, a protracted post-reproductive period exists. The mean age of menopause in human females is approximately 50 years, whereas in rhesus monkeys, the average age is approximately 25 years (Vollman 1977). Humans can live upward of 120 years, so their postmenopausal period can represent nearly 60% of their life span. This contrasts with female rhesus monkeys who have a maximum life span of 40 years and a post-reproductive period reaching up to 40% of the life span. Chimpanzees, on the other hand, experience menopause late in life, occurring around 50 years of age (Lecreux et al. 2008; Herndon et al. 2012). The maximum lifespan for chimpanzees is estimated to be

60-plus years. In this species, only 15% of a female’s life is characterized as post-reproductive. Perhaps a more conservative picture of the post-menopausal period would emerge if average life span were used as the denominator instead of maximal life span. In all primate species studied, this period of age-related infertility would diminish considerably.

Perimenopause, or that transitional state preceding menopause, occurs in humans anywhere from the mid-30s until the early 50s. There are many explanations underlying the variability in the timing of this event, and compelling evidence suggests that nonhuman primates also exhibit perimenopausal signs, including decreased fertility, irregular perineal swelling, and acyclic menstrual bleeding (Santoro et al. 1996).

Great Apes

Among the great apes, most is known about chimpanzee reproductive senescence. Chimpanzees (*Pan* spp.) are not dissimilar to humans with regard to reproductive decline. For example, both species show a loss in follicular development and more frequent fetal loss with advancing age. Despite incongruence in the exact timing of these events, the trajectory is identical. A departure between the two species is evident; however, with regard to the precise timing, humans thrive for years postmenopausally, whereas the end of reproductive life coincides more tightly with end of life in chimpanzees (Herndon et al. 2012). Data from other great ape species is more sparse – in both orangutans (*Pongo* spp.) and gorillas (*Gorilla gorilla*); reproductive characteristics are similar to humans; however, few data exist to document the occurrence of menopause in these species (Caro et al. 1995; Margulis et al. 2007).

Baboons

Data regarding the occurrence of menopause in baboons (*Papio* spp.) are scarce, despite the similarities in the characteristics between human and baboon females with regard to reproductive physiology and pregnancy. The life span of baboons is approximately 25–30 years, and data suggest that irregular cycles and increases in infertility begin to occur in the mid-20s. Despite direct evidence

for menopause in baboons, age-related reduction in fertility and increased inter-birth intervals strongly suggest a gradual loss in reproductive function (Strum and Western 1982).

Macaques

Rhesus monkeys (*Macaca mulatta*) are, perhaps, the best characterized of all nonhuman primate species with regard to menopause. Most data come from captive animals, and evidence suggests that menopause does occur in this species beginning around the age of 26 (Walker 1995). Lack of ovarian reactivity and diminished responsiveness to gonadotropin stimulation has been reported in this species (Walker 1995; Nichols et al. 2005). Although data are sparse in other macaque species (e.g., *M. nemestrina*, *M. fuscata*, *M. sylvanus*), the picture as a whole suggests that all macaque species undergo a period of reproductive quiescence late in life (Paul et al. 1993; Pavelka and Fedigan 1999).

New-World Monkeys

In new-world monkeys, whose maximal life span reaches the late 20s, a reduction in fertility begins to appear in the late teens. Histological analysis of the ovaries of squirrel monkeys (*Saimiri sciureus*) reveals a marked change in folliculogenesis as a function of age, with a sharp, rapid decline in primordial follicles occurring early in life followed by ovarian reorganization later in life, consistent with a loss of ovulatory function (Walker et al. 2009). Tamarins (*Saguinus* spp.) have similarly been found to undergo a period of reduced fertility (Tardif and Ziegler 1992).

Conclusion

Among primates, menopause is not a uniquely human phenomenon. It appears that many (if not all) primate species experience a decline in reproductive function with increasing age. Species' differences exist with regard to the precise timing, vis-à-vis the loss of reproductive viability in the course of the life span, however. Humans appear to have a longer post-

reproductive lifespan than other primate species, although this may be due, in part, to human's increasing longevity. The underlying phenomenon in all primate species suggests a decline of reproductive capacity due to changes in the hypothalamic-hypophyseal-ovarian axis.

Synonyms

[Primate sexual behavior](#); [Sociosexual behavior in primates](#)

Definition

Primate sexuality pertains to all the behaviors and set of strategies that both male and female primates adopt to achieve reproduction and/or pleasure. It is influenced by biological and ecological constraints, mating systems, and social dynamics.

Introduction

Primate sexuality is an extremely diverse and complex topic, and notwithstanding many decades of research since the pioneering work of Carpenter in 1942, we still do not have a unified understanding of the complexity of sexual behavior and the factors that influence sexual behavior in our closest relatives (Dixon 1998).

Here the topic will be presented and illustrated with well-known examples, primarily addressing ecology and mating strategies but also the systematics of primate sexuality. The entry will first explore the sexuality of solitary prosimians, then pair bonding and polyandrous *callitrichids*, then the sexuality of uni-male and multi-male catharrines, ending with apes.

When reproductive strategies of primates are explored from a socio-ecological and comparative perspective, it appears that most primates respond to food distribution and predation risk in a predictable manner. This, in turn, influences reproductive strategies, which are often the result of conflicting interests and responses of males and females (Camperio Ciani and Chiarelli 1993).

Primate Socio-Sexual Ecology

Sexual Behavior of Solitary Species

Nocturnal small size prosimians generally feed on insects. Given the distribution of their food source, these species are widely dispersed and at relatively low density. Females do not gain much advantage by clustering in groups and prefer to be solitary. The female bushbaby (*Galago moholi*) has a sealed orifice, and the vagina is locked in a way that prevents copulation outside of estrus. It has been observed that this is a reproductive feature that more closely resembles non-primate mammals than simians (Lipschitz et al. 2001). The only possibility that males have to control them and copulate with them is to roam in larger territories than females and actively search for fertile females, eventually competing agonistically with other males for access to female mates. Some of the solitary nocturnal prosimians show the most divergent sexual behavior compared to other primates.

A long-term study was conducted on the mating behavior of the solitary nocturnal, gray mouse lemur (*Microcebus murinus*) from Madagascar, and once the genetic relationships among more than 300 study animals were determined, the reproductive success of each individual male was quantified. It was found that individuals differ substantially in sexual behavior. The most successful male mouse lemurs roamed extensively in search of mates, had superior fighting ability, and copulated as early as possible. During these searches, contest competitions to temporarily monopolize the females were observed. Traditionally, in nocturnal prosimians, the outcome of this intersexual conflict has been studied from the male perspective, but it also depends on female mating strategies, such as manipulating the temporal distribution of sexual activity, advertisement, and mate choice. In this study on the gray mouse lemur, the relative importance of female mating strategies for the outcome of the sexual conflict was also investigated. The dwarf gray lemur is a species where females are always solitary during their activity period, except for a single night of receptivity. The study found that most females were receptive asynchronously, thus

favoring the best males access to them, by competing with other males and copulate with them, one after the other when receptive. Females did not exhibit any direct mate choice, although they exercised indirect choice for multiple mating. It was observed that they could copulate with up to seven different males and up to 11 times during their only single night of receptivity. Males, on the other hand, exhibited different mating tactics, and heavier males mated more and had greater reproductive success. However, genetic paternity assessment confirmed that most litters had mixed paternities showing that alternative strategies such as having extra copulation hiding from the best males and sneakers, defined as alternative males stealing copulation from unaware best males, were also effective. Male gray lemurs who switched between tactics were influenced by a number of socio-ecological factors such as short-term monopolization potential, mating opportunities, and the operational sex ratio (Eberle and Kappeler 2004).

Sexual Behavior of Pair-Bonded Primates

Among New World monkeys, Callitrichids (marmosets and tamarins) are diurnal and frugivorous in large part, and they dwell in South and Central America. In general, they present mating strategies that are more flexible and span from pair-bonded monogamy, occasionally to polyandry, and even, albeit rarely, to polygyny. These are the first primates where twin births and paternal investment have been observed in the field.

Sexual Behavior of Polyandrous Primates

Studies of wild tamarins and marmosets have focused on understanding polyandry, which is rare in primates outside New World platyrrhine monkeys. Such studies have shown that these species exhibit variable mating patterns, including cooperative polyandry, monogamy, and, more rarely, polygyny. Polyandry is thought to occur in this species due to the very high frequency of twin births and relatively large weight of infants, but small size of adults; this makes infant rearing particularly difficult and need extra help from non parents. Nonreproductive helpers (older offspring) and polyandrous males may serve as

alternative sources of help with infant care. The apparent causes of facultative polyandry in saddle-back tamarins are however quite different from those of the cooperative polyandry that has been studied in some bird species (Goldizen 1988).

On the contrary, other studies suggest that twinning could not have evolved before pair bonding in these species. Further, if theoretically possible and all else equal, males would always increase their fitness with a polygamy strategy, which makes polyandry an evolutionary puzzle. It seems however that adult females in this species pursue a number of strategies designed to coerce the male into remaining monogamous or eventually polyandrous (Dunbar 1995).

As an example, in cohabiting families of common marmosets (*Callithrix jacchus jacchus*), high-ranking individuals of both sexes living within the nest suppress reproductive behavior of both sexes of low-ranking individuals. In this competitive way, these animals maintain a monogamous breeding system. In newly established peer group nests of common marmosets, one male and one female rapidly dominate all others and overtly inhibit sexual behavior in subordinates of their own sex. The highest-ranking dyad starts to copulate and exerts reciprocal sexual inhibition on subordinates: male subordinates are inhibited or restrained from showing sexual behavior influenced by the dominant male, while subordinate females suffer from complete ovarian failure due to dominant female suppression (Abbott 1984).

Old World Monkeys

Old world monkeys are the most widespread non-human primates. They range and prosper across a variety of ecosystems in Africa and Asia. A general socio-ecological classification suggests that females, depending on resource distribution, cluster more or less in different size groups. Consequently, males try to control them with aggressive behavior, without allowing other males into the harem (uni-male groups). If the group of females is too large to be defended, then more males are allowed into the troop. In this case, males will compete within the troop and maintain rank hierarchies to gain sexual access to the

resident female. Members of the multi-male multi-female troop are generally discriminatory and try to outcompete possible intruders (Camperio Ciani and Chiarelli 1993). Alternatively, a review of a number of Old World monkeys suggests that the presence of single- or multi-male troops is associated with the duration of the breeding season: harems are more common when the breeding season is long, whereas multi-male troops are more common when the breeding season is short. The sex ratio of adults in a troop is likewise correlated with the length of the breeding season (Ridley 1986). However there is not a large contradiction of the two perspectives which both rely on female control by males; the first one is based on female number and the second one on female sexual availability.

Sexual Behavior of Uni-male Groups

The hamadryas baboons, (*Papio hamadryas*), which are quite unique among Old World monkeys, are organized in a multilevel structure (harems, clans, troop). In this species, contrary to most nonhuman primates but not to chimpanzees and humans, males tend to remain in their natal clans whereas females tend to move between clans and bands. This creates special bonds that develop between adult males. Within the harem, males show jealousy and herding behavior to keep their harem females in close proximity and fight possible intruders. In the harem, the only adult male has exclusive sexual access to its females. However, uni-male harems of hamadryas baboons cluster overnight on cliffs and safe areas together with other harems. These night clusters generate larger multi-male troops where each single harem is well subdivided. During this crowded situation, extra harem copulations are possible. To apparently reduce the cost of extra harem copulations, it has been shown that closely related males within a troop cluster together in genetically related clans, and each clan is well subdivided within the troop night gathering (Colmenares 1992; Kummer 1968).

Sexual Behavior of Multi-male Groups

When the size of the female group is too large or the duration of the breeding season is too short for females to be controlled by a single male, primates

form multi male-groups. In multi-male groups, the mating system and sexual access is mediated by social rank. However, the relationship between social rank and male reproductive success is not always straightforward, and female choice cannot be overlooked. In many studies without genetic information, clear results cannot be obtained.

In a study on wild long-tailed macaques (*Macaca fascicularis*), a relatively strong correlation was found between rank and reproductive success which was attributable to selective mating by the highest-ranking male during female fertile periods. The relations between mating success (copulations), reproductive success (fertilization), and dominance rank suggest that mating competition is involved. This could be expressed in adult males by having different sexual partners at different phases of fertility, either through male contest competition or female choice (De Ruiter and Van Hooff 1993).

A large sexual behavior and rank review explored mating (copulation) data from 32 studies of primate behavior, totaling 75 study groups, and found, despite conflicting reports, a consistent relationship between male dominance rank and mating success at least among animals of the same age class. These findings suggest that the relationship between dominance rank and mating success appears to be a function of the level of competition that males face in the group for access to cycling females. Data on genetic paternity indicate that these results hold not only for the number of copulations but also for absolute measures of reproductive success (fertilization).

Protection of own offspring and defense from infanticide and the tendency to kill other males offspring also shape primate sexual behavior, and infanticide happens both in uni-male and multi-males troops.

Male parental care in primates is much more common than in other mammals. Adult males of many simians species provide care for infants and juveniles, but this is not observed in prosimians. Among prosimians, care is often observed in the form of grooming, carrying, support in agonistic interactions, and protection from infanticide. For these behaviors to be interpreted as true parental care, males must selectively direct care toward

their own offspring, and this care must result in fitness benefits.

In a wild population of savannah baboons (*Papio cynocephalus*) with genetically determined paternity for 75 juveniles, agonistic disputes by adult males in support of juveniles have been measured in order to examine male care in this species. The results suggest that these baboons show true parental care. Adult males differentiate their offspring from unrelated juveniles and selectively support their offspring in agonistic disputes. This seems to contribute to rank acquisition and protect juveniles from injury and stress (Buchan et al. 2003).

On the other hand, long-term research on wild Hanuman langurs (*Presbytis entellus*) in the southern Nepal forest demonstrates attack on immature juveniles by adult males and corresponding active defense by resident males on immatures. This study recorded in detail and identified all attacks on infants by males. These attacks were analyzed in connection with male residency, genetic paternity, and sexual behavior. Adult males played a major role in infant defense. Only the genetic father or males who were residents when the infant was conceived were observed to protect infants. Males who immigrated after a female had conceived may later attack her infant and were never observed to defend these infants. It seems that the males take only copulations with potentially fertile females but not with pregnant females as clues for paternity. It seems likely that the risk of infanticide is an important determinant in female-male associations even in anthropoid primate multi-male groups (Borries et al. 1999). It should be noted that no convincing evidences ever suggested that males actually could associate copulation and female estrus with infant paternity; hence, the causal explanation for infanticide cannot be the absence of previous copulation with the offspring mother. The infant appears several months after copulation. The physiological mechanism of paternity is a cognitive acquisition unique to humans, and all studies aimed to confirm paternity recognition in primates failed or were disproved. The occurrence of these affiliations between adult males and infants raises the question as to whether males really care for their own offspring

preferentially and, if so, how male paternity confidence is mediated. Recent field studies of baboons suggest that male-infant relationships are mediated through affiliations between the males and the infants' mothers. The male protects the infants of mothers whom they had an affiliative relationship with but attack infants whose mother is unfamiliar, which seems a more plausible proximal cause of paternal behavior rather than actual genetic paternity (Busse 1985; Camperio Ciani and Chiarelli 1993).

Apes' Sexuality

Ape sexuality is highly variable, as in other primate taxa. In general, their sexuality is not substantially different from monkeys, although there are a few interesting exceptions. Orangutan males rape females. Gorillas are not particularly interested in sexuality and have high risk of incest compared to other primates. However, the most peculiar species is the bonobo, a species of chimpanzee, where sex is used in exchange of almost anything, and with anyone, to the point where these animals have been defined as "hypersexualized apes."

Rape in Orangutans

Male orangutans are solitary primates, quite similar to the much smaller and primitive nocturnal prosimians, and like them, they tend to exploit larger territories than females and feed on sub-optimal fruit to attract females in their territory. Adult males keep other males at distance with specific loud calls that are intended to reduce male-male agonistic competition, which can be extremely violent but does not function to attract fertile females. In a long-term study in Tanjung Puting in Borneo, the large adult male indulged to copulate forcefully with the females found on their own territory. These observations suggested that orangutan might rape females. It is a form of rape more sexual than aggressive; in fact males who rape, beside obtaining a copulation, do not succeed in herd, lead, or coerce the raped female, as it happens in aggressive and dominant behavior in other primates (Galdikas 1981). Indeed, rape of females could occur on a daily basis, irrespective of female resistance (Nadler 1977).

Gorillas and Incest Behavior

The sexual behavior of free-ranging mountain gorillas (*Gorilla beringei beringei*) was studied at Karisoke Research Centre. In this ape species, immature males and females develop sociosexual relationships with both peers and adults, and these relationships often lead to mating between natal females and males who are "familiar" partners. This can cause incest with a possible risk of inbreeding. Immature males may copulate with both nulliparous and parous females. However, among adult males, a substantial level of within-group reproductive competition has been observed, which might counteract the risk of inbreeding. During field observations, it has been found that more than one unrelated silver-back male can reside in the same all-male group; however, if the female joins the group, these males become intolerant of each other. Female-female competition for opportunities to copulate with specific males, possibly the best ones, has also been observed. This female-female competition might also contribute to reduce the risk of inbreeding (Watts 1990).

Bonobo Sex for Resources and Sex as a "Social Vehicle"

The most peculiar habits in ape sexual behavior pertain to bonobos (*Pan paniscus*). In this species, sexuality is mostly non-conceptive and is used for a large variety of sociosexual interactions, such as appeasement, in exchange for food, and as a social bond within the group, and is frequently performed both in adult and juvenile relationships. Sexual behavior with non-fertile females, by same-sex partners, and adult-immature dyads is not a product of captivity and occurs both in wild and captive bonobos. Proposed functions of these wild sexual behaviors, in social primates generally, include practice for immatures, paternity confusion, exchange, and communication as well as appeasement (Manson et al. 1997). The evolution of non-conceptive sexuality in bonobos and chimpanzees (*Pan troglodytes*) can be examined from a functional perspective. Bonobos and chimpanzees have three functions of sexual activity in common (paternity confusion, practice sex, and exchange for favors), but only bonobos use

sex purely for communication about social relationships. Bonobo hypersexuality appears closely linked to the evolution of female-female alliances in other primate species. It has been suggested that these female alliances are made possible by relaxed feeding competition, favored through their effect on reducing sexual coercion, and a high level of sexual activity is ultimately responsible for the relaxed social conditions in bonobos. Perhaps female-female alliances allowed the evolution of this very peculiar form of communication through sexuality (Wrangham 1993).

Primate sexuality is not finished with this general classification from solitary prosimians to multi-male multi-female Old World monkeys. The sexual variety in primates is just started. Firstly, most or all apparently monogamous species show evidence of extra-pair copulations. Further, in most primates, sexuality does not finish with copulation, since sperm competition occurs, and sperm competition induces a variety of adaptations that originated in many species. Further, sexuality in primates is not limited to copulation for fertilization, as it has been shown for bonobos, but sex is also used for pleasure like masturbation, both in males and perhaps more rarely in females, sex with immatures, etc. Finally, even in a short exploration of primate sexuality, it is not possible to avoid mentioning primate homosexuality.

Other Relevant Aspects of Primate Sexuality

Consorting

First defined by Carpenter (1942) studying rhesus macaques (*Macaca mulatta*) in Cayo Santiago, “consortship” has a central role in the study of the mating behavior of multi-male group living primates. In general, among mammals, interactions between the sexes, particularly those of an affiliative nature, are associated with, and are often limited to, the period of copulation and only occur during female estrus. However, various species of primates exert their sexual behavior during the mating season by developing this special reciprocal bond between two individuals of the opposite sex of variable duration called

consorting. During this phase, the two partners groom each other, keep close proximity, and sometimes abandon the group crowd. The reason why such cohesive male-female bonds persist beyond estrus in nonhuman primates remains partly obscure. Protection from male infanticide has been offered as a potential benefit to females of bonds with males in a variety of primates, including mountain gorillas and gibbons (Palombit 1999). Primate consorting can be conceptually understood as a variation among male/estrous female dyads, which is characterized by three functionally relevant dimensions: mate assessment, courtship, and mate guarding. Here, a courtship component, but not a male mate-guarding component, predicts the rate of fertile mating (Manson 1997).

Copulation Dynamics

Primates generally copulate dorsoventrally, with the exception of orangutans and bonobo apes that indulge also in ventro-ventral copulation like in our species. The male penis is equipped with an internal bone called the *baculum* that assists with intromission during erection. Primate penis, testis morphology, and size are all extremely variable and species specific. In the case of macaques, as an example, the various species are possible to be classified exclusively on the morphology of their penis which is highly variable. The length of the penis and the size of the testis are good indicators of the presence of sperm competition and male-male competition in copulations. Even mounting behavior varies a lot in duration and sequence. In some case, copulatory dynamics reach complexities that have to be learned via trial and error during infancy, as in the case of the macaques, in which males have to climb and hold the rear legs of the female partner to achieve penetration. Among macaques, as an emblematic example, there are species which mount a single time and ejaculate very rapidly. Other species instead reach ejaculation after multiple mounts (e.g., more than ten mounts in sequence in some instances). In these last species, ejaculation takes longer and requires prolonged time of close proximity among partners. In these cases, consorting is more frequent (Camperio Ciani and Chiarelli 1993).

Sperm Competition

Sperm competition might be the inevitable consequence of polyandrous mating behavior or extra-pair copulations. It can happen if two or more males inseminate a single female. It has been demonstrated for a wide variety of animals that males adapt to sperm competition behaviorally, physiologically, and morphologically, e.g., by evolving relatively large testes size to produce more sperm. Sperm competition involves competition between the gametes of two or more males of a species for fertilization of a given set of ova. Sperm competition is widespread among mammals, as in many other groups of vertebrates. If the reproductive organs of male mammals are viewed as an integrated system for production and delivery of spermatozoa (and accessory glandular secretions) to females, then it is logical to assume that sperm competition might influence the evolution of all parts of the system, as well as associated physiological mechanisms (e.g., testicular endocrinology) and behavior (e.g., copulatory patterns). Comparative studies of genital anatomy and sexual behavior in male primates show that penile morphology, and copulatory patterns tend to be more specialized in species which have a multi-male or dispersed (nongregarious) mating system. The penis may be longer and more complex morphologically in such species. Copulatory patterns involving a series of intromissions or prolonged single intromissions are more common in multi-male systems than in species with a monogamous mating system. All pair-living primates investigated so far are found to have relatively small testes, suggesting a single male mating system (monogamy). Sexual selection may have favored the evolution of sperm competition in species where females mate with a number of males rather than with a single partner. Relative testis size is also greatest under such conditions and larger testes occur in some nongregarious or seasonally breeding prosimians, as well as in anthropoids with multi-male mating systems.

Data on interspecific variation in ejaculate quality further show that primate species with relatively large testes also produced ejaculates with relatively large volumes, high sperm counts,

high sperm motility, and more motile sperm. Hence testes size, after controlling for the effect of body size, can be related to breeding systems in primates, all circumstantial evidences of adaptations to sperm competition (Møller 1988).

Sperm Plugs

Adult males have evolved sperm plugs, another way to control fecundity of females. Sperm plugs are present in certain species of primates such as *Macaca fascicularis*. These sperm plugs are a clotted portion of the ejaculate that obstacle new intromission and copulation in the female's vagina. Moreover, sperm plug integrity informs the male that the female did not copulate after him. Sperm plugs can be manually or olfactory inspected, recognized, and removed by single males. Sperm plugs act as a lock or a signature to inform males about recent copulatory behavior of a female. Sperm plugs seem to be most frequent in those genera where females commonly mate with multiple partners and least frequent in genera where females are primarily monogamous or belong to polygynous units. Perhaps sexual selection has played an important role in the evolution of seminal coagulation and copulatory plug function in primates (Dixson and Anderson 2002).

Sneakers and Rape

Sneakers are those males that use an alternative sexual strategy to achieve copulation with females. These males do not compete to achieve a relevant rank and copulatory right, but rather sneak in proximity of a (willing) female to steal a copulation, and eventually a fertilization, unseen by other males. Rape instead happens if these sneakers approach an unwilling female and force her to copulate before the resident male(s) realize. A clear example of sneaker behavior has been studied in the mating behavior and paternity of offspring of patas monkeys (*Erythrocebus patas*). These primates were studied in wild conditions at Kala Maloue National Park, Cameroon. Sneaky mating occurred during both one-male and multi-male situations. If resident males could witness sneaker copulations, they would then perform compensatory mating with the female. This behavior might be effective for a dilution of

sneaker sperm. The presence of sneakers in wild patas monkeys explains the discrepancy found between observation of mating and paternity identification (Ohsawa et al. 1993).

Extra-Pair Copulation

Asian lesser apes are called gibbons and siamangs and live in strictly monogamous groups. These monkeys are very monogamous and there is no dimorphism at all among partners. Even the male sexual morphology of the penis resembles that of the clitoris and labia of the female. The absence of dimorphism has long been considered a clear evidence of strict monogamy. However, also in these strict monogamous species, not everything in their sexual behavior is clear and straightforward. In a study conducted in the rainforest of Thailand, it has been shown a clear evidence for extra-pair copulations in white-handed gibbons. Researchers found that extra-pair copulations constituted 12% of all recorded copulations. Extra-pair copulations were present among three free-ranging, well-habituated groups. These extra-pair matings involved one adult already-paired females and three adult already-paired males. Extra-pair copulations were explained by the researchers as an effort to breed with a partner of superior quality to the current mate and possibly as part of a strategy to forestall infanticide. In any case, in these highly monogamous primates, it has been shown that monogamy is not absolute, and extra-pair mating occurs (Reichard 1995).

Male Masturbation

Male and female nonhuman primates from all living taxa are known to perform auto-sexual behaviors (masturbation) implying that masturbation is a facet of the primate sexual repertoire. At a proximate level, masturbation satisfies sexual desires leading to a hormonal state of relaxation and reduced aggression in both sexes. This might be of importance above all in social living primate species. Ultimately, masturbation might be beneficial for males since it helps to discard old and low-quality sperm from the genital tract, allowing the production of new sperm with enhanced fitness. For example, in Japanese macaques (*Macaca fuscata*), masturbation occurred over

the whole year; however, it was more frequent during the mating than during the non-mating periods. Notably, masturbation with ejaculation is restricted to the mating period. In this species, male mating success correlates positively with social status. Both rate of masturbation only and masturbatory ejaculations increased as male social status and male mating success declined. Lower-ranking males had higher rates of masturbation, and they spend more time masturbating than higher-ranking males. Lower-ranking males also have higher proportions of ejaculates for masturbation, while higher-ranking males use most of their ejaculates for mating.

Female Masturbation

In bonobos, the species is characterized by a high frequency of ventro-ventral copulation, a prolonged period of female sexual responsivity and homosexual behavior, especially between females in the form of genito-genital rubbing, which can be considered a reciprocal masturbation. Both wild and captive female bonobos exhibit this form of non-copulatory sexual behavior called genito-genital (GG) rubbing – in which two females rub their genital regions together, producing a reciprocal masturbation. For female masturbation, however, an ultimate explanation is still lacking. It seems that GG-rubbing in bonobos occurs in several contexts and may serve several functions, including tension reduction and reconciliation. The hypothesis is that GG-rubbing reinforces or at least reflects social bonds. Bonobo females might GG-rub to generate pleasure rather than to reconcile conflicts, reduce tension during feeding, signal social status, or to attract mates (Manson et al. 1997).

Homosexual Behavior

Homosexual behavior is defined as genital contact, genital manipulation, or both between same-sex individuals. Available data indicate that this behavior is phylogenetically widespread among the anthropoid primates, but apparently absent among prosimians. There is a particular difference however from human homosexuality since in all primate studies with some evidence of homosexual behavior, no permanent homosexual

individuals have been observed, but on the contrary homosexuality is only occasional (Camperio Ciani et al. 2015; Vasey 1995). (See primate homosexuality for further information.)

Conclusion

This synthesis of variety in primate sexuality illustrates most of the possible primate strategies through which males tend to increase their reproductive fitness and how females exercise choice and partner selection. In primate sexual conflict, ecological and social variables suggest new solutions and strategies that sometimes favor females over males or vice versa but still select for optimal reproductive success. Primate sexuality should be an essential topic for anyone interested in the sociosexual behavior of our human species.

Primate Sperm Competition

Sean Coyne
University of Chicago, Chicago, IL, USA

Synonyms

[Competitive mating](#)

Definition

Competition between the sperm from two or more males for the fertilization of a given set of ova (Parker 1998).

Introduction

The definition given above can apply to all sexually reproducing animals. However, all primates have internal fertilization, meaning that the anatomy and physiology of the female reproductive tract are the only environment in which the sperm of the various males compete for access to the ova (Dixson and Anderson 2004). Furthermore, there are factors that affect the degree of competition among males to gain access to a female's reproductive tract, and this competition is played out at the physiological (e.g., testis histology, ejaculate output) as well as behavioral level.

Sperm Quality

There is a common assertion in animal behavior that sperm are “cheap” (relative to the “expensive” ova of females). While this comparison is superficially accurate, sperm do have a non-negligible physiological cost and are not an infinite resource. Competition among males to fertilize an egg involves physiological processes as well as behavior at both the individual and group levels. To understand sperm competition in nonhuman primates, then, it is necessary to explore all these factors.

Ejaculate Physiology and Frequency

In many species of primates, the ejaculate can be split into two fractions: a liquid and a coagulum (Wildt 1986). The degree to which the coagulum contracts and forms a solid barrier varies between species, but in many it forms at least a partial plug (e.g., rhesus macaques) or becomes a fully substantial plug (e.g., chimpanzees, ring-tailed lemurs). Regardless of the type of barrier this coagulum forms, as it hardens and contracts, it releases sperm into the reproductive tract. There

are two (not mutually exclusive) hypotheses about the function of these coagulates: (1) it helps males by preventing the loss of sperm via backflow out of vagina and/or (2) it might obstruct other males from depositing their own semen thus preventing direct sperm competition in the female reproductive tract (Dixon 2012). These plugs play a crucial role in primate sperm competition because they contribute a sizable portion of sperm to the overall ejaculate and may, in one way or another, increase the chances of fertilizing a female. However, unlike in many insect and bird species, the order in which male primates copulate with a female seems to play little role in the likelihood of fertilization. For example, in birds, the last male to mate with a female before she ovulates is most often the one to fertilize the egg due to sperm storage mechanisms in these species. Most mammals, including primates, do not store sperm in the reproductive tract. Therefore, the only “mating order” effects one would expect in primates relates to the role of the sperm plug. Specifically, the first male to form a plug with a female (and by extension, the longer his plug lasts) would increase his chances of fertilizing the egg. This phenomenon is not really an order effect, however, of the kind we see in birds and insects.

In addition to the physiology of the ejaculate, the frequency with which a male ejaculates can affect the quality of his semen. For example, in an experiment on captive chimpanzees, semen samples were collected hourly over a 5-h period. Over that time period, sperm count in the ejaculate declined by 54% (Marson et al. 1989). Therefore, it is not necessarily the most competitive strategy to constantly ejaculate with every female possible because sperm resources can become depleted. This is where male choice/behavior in concentrated mating effort can be very important in sperm competition (discussed below, see “[Male Behavior](#)”).

Social Organization

One of the biggest factors to affect the degree of sperm competition between males is the mating system of that species (or group). For example, males that live in multimale-multifemale groups with promiscuous mating systems have much more competition per reproductively active

female than relatively solitary monogamous pairs, who by definition should have exclusive access to a female and little to no competition from other males. Interestingly, relative testes size (the ratio of testes to body weight) is heavily predicted by mating system. Primates with multimale-multifemale mating systems have much larger relative testes size than those in polygynous (e.g., harems, one-male units) mating systems, which in turn have larger relative testes size than those of monogamous primates, who have the smallest relative testes (Dixon 2012). The relative size of the testes is important because it determines the seminal volume and amount of sperm an individual can produce. Therefore, if multiple males are competing to impregnate a single female, the male with the greatest seminal volume or highest sperm count has a better chance of fertilizing a given ova.

Male Behavior

As mentioned above, while sperm are “cheap” to produce, male ejaculate quality can decline from overuse. Males can engage in sperm competition by timing their ejaculations to coincide with the peak of female fertility. For example, many female primates advertise fertility through obvious and exaggerated signals such as swelling or skin color (e.g., baboons, rhesus macaques, Higham et al. 2011). Males who both correctly interpret these signals and concentrate mating effort at these times can reduce the number of ejaculations needed in order to fertilize an egg. By successfully concentrating mating effort at times of peak female fertility, males can not only increase their chances of fertilizing that particular female but they can also reduce the number of ejaculations spent per female. This reduction in number of ejaculations allows males to keep a larger reserve of sperm (i.e., nondepleted semen) for future mating opportunities.

Alternatively, males who do not ejaculate very often or at all can develop different problems with sperm quality. Specifically, if sperm are stored too long, they can degrade or develop abnormalities. A possible solution to this problem is masturbate to expel the degraded sperm in order to have only the best quality sperm available if a mating opportunity presents itself. However, this strategy is not

without risks because a male can never know when a future opportunity will arise. If a male masturbates too soon before a mating opportunity occurs he may suffer a cost such as being in a refractory period (i.e., the period of time it takes to recover and be able to ejaculate again after previously ejaculating) when a sudden mating opportunity arises. Males must make behavioral decisions based on likelihood of mating opportunity. One common proxy for mating success is male dominance rank, because the highest ranked males often mate much more often than lower ranked males. If this is the case, one would expect that lower ranked males (and/or less successful males) should masturbate more frequently, since they are mating less often, and are therefore more likely to have degraded or abnormal sperm. This phenomenon was confirmed in a study of Japanese macaques by Thomsen and Soltis (2004).

Conclusion

Despite the apparent “cheapness” of sperm, there is still fierce competition among males about how to “spend” this limited resource with females in order to maximize their chances of fertilizing a female’s ova. The degree to which males are forced to compete is heavily determined by the mating system of their group, with the highest rates of competition occurring in promiscuous multimale-multifemale groups. Quality and quantity of the sperm itself can vary, due to factors such as the effectiveness of sperm plugs or the rate of ejaculations. Male behavior can also affect sperm competition, in both positive (e.g., timing mating effort to coincide with female fertility) and negative (e.g., masturbating before a mating opportunity) ways. Therefore, due to the complex nature at which this competition plays out, it is important to consider all the potential factors that are working together.

[Elementary technology](#); [Nonhuman primate tool use](#); [Physical cognition](#)

Definition

The use of an external object by a nonhuman primate to extend the function of its hand, foot, or mouth to help attain a desired outcome.

Introduction

Although one of the earliest scientific observations of tool use by a nonhuman primate (wild chimpanzees) was reported in the nineteenth century (see Savage and Wyman 1844), the modern study of primate tool use can trace its origins to Jane Goodall's (1968) fieldwork in Tanzania. It was there at Gombe National Reserve that her careful observations of chimpanzees using sticks to forage for termites helped change the view that tool use was a uniquely human ability (e.g., Oakley 1949). Today, reports of tool use among wild and captive primates are widespread and include the use of many objects for many purposes. Thus, in addition to using sticks to forage, primates use stone hammers to crack open nuts, folded leaves for drinking water, poles as ladders, and perhaps even branches and stones as weapons. What follows is an exemplar-based summary of primate tool use in these categories. For a comprehensive list of primate tool use and competencies, see Tomasello and Call (1997) and Shumaker et al. (2011).

Stick Tools and Foraging

Among all nonhuman primates, chimpanzees are the most reliable and frequent users of tools, and a chimpanzee fishing for termites is perhaps the most iconic image of a nonhuman primate using a tool (Povinelli 2000). To fish for termites, chimpanzees use tools that consist of a blade of grass, a strip of bark, or a twig stripped of its leaves. This last tool is of special interest because the chimpanzee modifies an object (a twig) to make it better suited for achieving a particular goal. Once the chimpanzee has an appropriate stick, it inserts the tool into a termite mound. Inside the mound, the termites bite the intruding stick. The chimpanzee then slowly withdraws the stick, pulling out masses of edible insects (Goodall 1968).

Blonde capuchin monkeys also use sticks to fish for termites (Souto et al. 2011). In contrast to chimpanzees who fish for this insect on the

ground, blonde capuchins fish for termites above the ground. With their bodies in a squatting position, these monkeys use their semi-prehensile tail to anchor themselves to a horizontal branch in a tree, which allows them to use both of their hands to fish for the termites. This activity begins with the capuchins firmly and quickly tapping the exterior walls of the termite nest, tearing off a small branch from the tree, inserting and rotating the branch into the nest, removing the stick and inspecting it, eating the termites attached to it, and then reinserting the stick into the nest with one hand and tapping the nest with the other hand. Tapping the walls of the nest and rotating the stick have not been reported for any other primate (Souto et al. 2011).

In addition to procuring insects, primates use tools to help them obtain and eat vertebrate prey. Forest-dwelling chimpanzees hunt and kill colobus monkeys and then use sticks to dig out marrow from these animals' bones and to clean out the orbits of the skulls after having eaten the eyes (Boesch and Boesch 1990). Savannah-dwelling chimpanzees hunt bush babies (small nocturnal prosimians) within tree cavities using a tree branch that they sometimes sharpen with their teeth. The method of capturing the prey varies. Sometimes a chimpanzee jabs the prey to rouse it from the tree hollow and then chases down and kills the prey (Pruetz et al. 2015). Other times, a chimpanzee forcefully jabs the stick multiple times into a tree hollow to injure the bush baby and then extracts the skewered prey (less often) or reaches into the tree cavity to extract the immobilized animal (more often). Used in this manner, these sticks function more like spears than rousing tools.

Orangutans use stick tools to extract honey from bees' nests (van Schaik et al. 1996). The orangutans begin by selecting a live branch from a tree near the nest and then remove the twigs and leaves from the branch. In some cases, orangutans use their teeth to strip the bark and to chew the tip of the branch to fray, split, or flatten it. The tool is sometimes held in the orangutan's teeth when it is being used; other times the branch is held in the primate's hand when it pokes at the nest, which prompts the

bees to exit. The orangutan then uses the stick to extract honey from the nest.

Orangutans also use sticks to pry open and remove the hairs of *Neesia* fruits (van Schaik et al. 2003). When these large fruits ripen, the hard and ridged husk partially splits open. The seeds inside the fruit are edible and desired by orangutans, but are difficult to obtain because they are surrounded by a mass of irritating hairs. To extract the seeds, orangutans select a twig about 12 cm long and use their teeth to strip it of the bark. While holding the stick in its mouth, an orangutan inserts the tool into the cracks of the split husk and scrapes out the hairs by moving them toward the fruit's apex. The orangutan then scoops out the exposed seeds using one of its fingers or the handheld tool (van Schaik et al. 1996).

Hammers and Anvils for Foraging

A New World monkey, the capuchin, uses hammers and anvils to crack open nuts and seeds. These hammers and anvils are often stones: rounded handheld stones for the hammer and flat larger boulders for the anvils. These tools are sometimes made of wood, such as when capuchins use a detached tree branch as a hammer and the roots of a tree as an anvil (Aguilar et al. 2014). Once a monkey finds an appropriate hammer and anvil, it places an object such as a palm nut on the anvil. While standing or sitting, the monkey holds the stone hammer in both hands and pounds the nut. This pounding involves lowering the hammer stone with arm and shoulder movements, but when more effort is required, the standing monkey lifts the stone to shoulder height before pounding the nut forcefully with the stone. After striking the nut, capuchins frequently inspect and reposition it (Fragaszy et al. 2004).

An Old World species, long-tailed macaques, uses stones and shells to detach or break oysters. One behavioral form, ax hammering, is used to crack open sessile rock oysters by chipping the oyster with the edge or point of the tool. A second behavioral form, pound hammering, is used to crack open an unattached food item that is placed

on an anvil (Tan et al. 2015). More specifically, ax hammering uses a tool's points, has a faster strike rate, uses a precision grip, has a wider range of motion, has a smooth strike recoil, and is performed using a variety of postures. In contrast, pound hammering uses a tool's face, starts from a seated posture, has a slower strike rate, uses a power grip, does not usually have a smooth strike recoil, and is performed toward the horizontal plane where the animal is seated (Gumert et al. 2009). Macaques select different stones suited to the different behavioral forms.

Ivory Coast chimpanzees also use stone hammers and anvils to crack open nuts. Like capuchin monkeys, chimpanzees select a smaller stone as a hammer and a larger flat stone as an anvil and may even transport these objects to preferred locations that over time form recognizable primate archaeological sites. One such site at Tai National Park unearthed 4,300-year-old collections of stone tools used by chimpanzees (Mercader et al. 2002). In addition to stone tools, chimpanzees have also been observed using a log as a hammer and the roots of trees as anvils to open nuts (Boesch and Boesch-Achermann 2000).

Fluid Transportation

Most examples of primate tool use are related to the procurement of food. It is perhaps not surprising then that primates also use tools to help them obtain water for drinking. Chimpanzees dip twigs, herb stems, and pieces of grass into water that collects in the recessed areas of a tree (Byrne et al. 2013). After they insert the twigs and stems into the cavities, chimpanzees withdraw these tools and suck the water that clings to them. Chimpanzees also use sponges made from masses of leaves in a similar manner (McGrew 2010). To manufacture these sponges, chimpanzees compress several fresh leaves into an absorbent mass (Sousa et al. 2009). Similarly, chimpanzees use leaf sponges to absorb residual liquids from fruit and the brain tissue from the skulls of vertebrate prey (Beck 1980). Wild bonobos also make sponges out of moss and use these similarly to how chimpanzees use leaf sponges (Hohmann

and Fruth 2003). Captive bonobos and chimpanzees use the shells of fruits as containers for water (Gruber et al. 2010).

Examples of sponging by wild orangutans are rare, though they do sometimes use crumbled leaves to absorb water and leafy branches to “scoop” water from holes in trees (van Schaik et al. 2006). Orangutans living in sanctuaries use cloth, plastic bags, and husks to absorb water (Galdikas 1982). Capuchin monkeys are also known to dip small branches with leaves into tree cavities that contain water (Aguilar et al. 2014). In an urban setting, these monkeys use bread seemingly as a sponge to absorb water (Aguilar et al. 2014). Wild capuchins also use leaves as cups to retrieve water from holes in trees (Phillips 1998).

Climbing and Other Motion Assists

Wild gorillas are not known to use tools. One exception was the observation of a Western lowland gorilla using a handheld detached tree branch seemingly as a walking stick to test the depth of the pool of water she was crossing (Breuer et al. 2005). In another observation of tool use by a wild gorilla, the animal used a detached tree trunk as an object for support. This gorilla held on to the trunk with one hand while outstretched and dredging for aquatic herbs with her other hand. After she finished dredging, the gorilla used the trunk as a bridge to cross a deep section of swamp (Breuer et al. 2005).

In a report of putative tool use by a wild gorilla, a female wild mountain gorilla was observed extending a bamboo pole to her infant who then climbed the pole so that it functioned as a ladder (Grueter et al. 2013). In this case, the observers could not rule out an alternative explanation based on happenstance: Perhaps the mother gorilla simply happened to have a pole in her hand when she looked down at her infant, who then began climbing the makeshift ladder.

Wild orangutans have been observed using tools to facilitate travel. One such report consisted of orangutans who first bit through the bottoms of vines to free them and then used the vines to swing

across a gap in the forest (van Schaik et al. 2006). There are also numerous reports of captive orangutans propping and climbing sticks to secure suspended food (e.g., Yerkes 1916) and captive chimpanzees behaving similarly when they vertically balance poles and then climb them to get bananas suspended overhead (e.g., Köhler 1927). Young chimpanzees will also use poles as ladders to clamber over a high fence (Menzel 1973) and will jam sticks into seams in a fence, creating pitons that they use to climb over the fence (McGrew et al. 1975).

Agonistic Encounters Using “Weapons”

Discussions of primates using tools during agonistic encounters are controversial. The core of the controversy is whether primates use tools as purposeful (goal-directed) weapons to ward off or disable conspecifics, humans, or even inanimate targets during these encounters or whether primates simply use objects as part of a display to make themselves look larger and noisier (Washburn and Jay 1967). The use of objects during agonistic encounters often appears purposeful (van Lawick-Goodall 1971). For example, wild chimpanzees wave and brandish large branches during aggressive interactions with other chimpanzees. During these interactions, chimpanzees adopt a bipedal position, hold the branch in one hand, raise it, and forcefully bring the branch down toward another chimpanzee. The stick-wielding chimpanzee often lets go of the stick before it contacts the target, though the attacking chimpanzee does sometimes continue to hold the stick when clubbing the other chimpanzee (van Lawick-Goodall 1971).

There are also reports of chimpanzees using objects to attack inanimate objects. One such report involved a captive chimpanzee who used a long branch (about 180 cm) to take down a camera-equipped drone. The attack sequence began with the chimpanzee collecting the stick and then climbing some scaffolding while holding the branch. As the drone came closer, the chimpanzee made two long sweeps with the branch she

held in her left hand, contacting and downing the drone with the second sweep. To the researchers who observed this event, the chimpanzee's chain of responses appeared purposeful (see van Hooff and Lukkenaar 2015).

Humans also have been the targets of apes using objects during agonistic encounters. For example, Cross River (Cameroon) gorillas have been observed throwing grass at humans. During other encounters, a gorilla threw a detached branch toward researchers, and a group of gorillas threw fistfuls of grass at a man who threw stones at them (Wittiger and Sunderland-Groves 2007). Whether these encounters reflect an understanding that a particular action produces a particular outcome or were simply a part of an unconditioned display is unclear.

Conclusion

Although there are numerous examples of tool use in nonhuman primates in the wild and in captivity and there are many studies of these animals' behavior both in their natural environments and in laboratory settings, it remains for future studies to answer three key questions about primates' tool use. The first question is: How does tool use develop? Despite an impressive range of tool use behavior (see Boesch and Boesch 1990; McGrew 2013), observations of primates using tools do not usually provide information about how this tool use came to be, particularly in terms of the prior experiences necessary for it. The interrelation between learning and developmental processes seems critical because, for example, capuchin monkeys less than 5 years old rarely manage to use a hammer and an anvil to crack open more resistant nuts (Fragaszy et al. 2013); chimpanzees may require almost 10 years to master this same behavior (Boesch 1993). What role learning plays in the formation of tool use remains to be investigated and debated (Machado and Silva 2003; Povinelli 2000; Tomasello and Call 1997).

The second question is: What do primates understand about their tool use? This is a difficult question to answer because "understand" is not a

well-defined scientific concept (Pear 2001). The answer depends on the definition of the term (see Machado and Silva 2003). For example, if understanding is demonstrated in the same way that concept learning is demonstrated – i.e., requiring that animals make a common response to a class of stimuli that have certain specifiable characteristics – then primates are demonstrating some degree of understanding when using tools in that they use different tools in different contexts (Boesch and Boesch 1990). If "understand" means "able to discriminate between tools on the basis of functionality," then the answer may depend on, among other factors, the species of primate and the testing conditions (cf., LeFauve and Margulis 2015; Povinelli 2000). If "understand" means being able to use the right tool at a particular moment across a range of problems in the absence of explicit training, then it is unlikely that primates understand their tool use (e.g., Povinelli 2000). If "understand" means "able to verbalize a cogent explanation," then primates do not understand their tool use. But if "understand" means simply "behaving in a goal-directed manner," then primates understand their tool use (Pear 2001).

The third question is: Why do some captive monkeys and apes use tools in ways that their wild conspecifics do not (Haslam 2013)? Examples involving gorillas are especially illustrative because these primates rarely use tools in the wild, but do use them in captivity and in laboratory studies. Animals bring to artificial environments what evolved in their natural environments (Timberlake 1990). In that sense, differences between captive and wild primates' tool use may reflect differences in performance rather than ability. The simplest explanation for differences in tool use between these two groups of primates relates to variation in the availability of materials for tools. In captivity, there are a greater variety of materials for tools than in an ecological niche. As such, opportunity more than necessity may underlie differences in primates' tool use in different environments (Koops et al. 2012). It remains for future studies to identify the variables that bring about tool use or constrain its expression.

Principles of Geology

Ian J. Smalley

School of Geography, Geology & the Environment, University of Leicester, Leicester, UK

The full title of this famous book is descriptive and informative: *Principles of Geology; being an attempt to explain the former changes of the Earth's surface, by reference to causes now in operation*. Underpinning everything is the concept of “deep time,” the idea that vast amounts of time were available in which geological activity shaped the world. Gradual processes could achieve the necessary shaping and construction; catastrophic events were not required.

John Murray in London published the first volume in 1830; the second volume appeared in 1832, and the third in 1833. Charles Darwin took

the first volume with him when he set off in the Beagle in 1831; the third volume reached him in Valparaíso in 1834.

The *Principles* was a very successful book; 11 editions were published in Lyell's lifetime and a 12th was in preparation at his death. A facsimile version of the first edition has been published by the Chicago University Press and this benefits from a bibliographical section by M. J. S. Rudwick. A successful one volume version has been published by Penguin. This has been edited by J. Secord and concentrates on the philosophical aspects of Lyell geology. The introduction by Secord is an excellent discussion of all aspects of the *Principles* from its conception and execution to its effects and reactions.

The *Principles of Geology* was a highly persuasive book. In clear, straightforward prose, Lyell described geological changes now at work and presented evidence of calm, undisturbed geological conditions on the earth's surface in the past. The book was read widely. By 1841, it was in its sixth edition. It won enthusiastic adherents, among whom was Charles Darwin.

Richard Holmes (2009), in his study of science and the romantic generation considered Charles Lyell and the *Principles of Geology*. He records that the initial publication would finally use scientific evidence to reject the Biblical account of short-scale creation of the earth, as maintained by every authority from Cuvier and Paley to Buffon and Buckland. Lyell's proposal of a "deep time" corresponded to the "deep space" cosmology of William Herschel. It would ultimately, wrote Holmes, provide the supportive authority for Charles Darwin, his great friend, to accept the deep time necessary for evolution by natural selection to take place.

The text was briefly summarized by Bailey (1962, pp. 81–94) and reviewed at greater length by Wilson (1972, pp. 262–339). In the first volume (1830), Lyell offers a history of geology; he wants geology to be separate from cosmogony in the same way that history is separate from theories of the creation of mankind. In chapters 2–4, he traces the history of the subject up to the founding of the Geological Society of London in 1807. He gives a full appreciation to the works of James

Hutton (he was born in the year, 1797, that Hutton died). In chapters 6–9, Lyell considers a theory to account for the life-succession in the rocks of Europe and North America. He suggests a correlation between changes of local climate and the geological distribution of the land and sea. Lyell explained his views on the changes in the organic world that would have followed on changes in the inorganic, he spends the rest of volume 1 discussing historical modifications of geography caused by rivers and springs and seas (chapters 10–17), volcanoes (chapters 18–22), and earthquakes (chapters 23–26).

In volume 2, chapters 1–4 are devoted to a statement and criticism of Lamarck's theory of evolution which proposed that variation of species, whether inborn, as "the effects of internal sentiment," or acquired as reactions to the environment, was inheritable, with results that knew no limit. Lyell argues that species are fixed in the sense that limits have been set to the variability of each and every one. Chapters 5–7 deal with the geographical distribution and means of dispersal of species, and chapters 12–18 consider burial of fossils and the influence that life has had upon the surface of the earth. Lyell is quite clear that the geological record proves that man is a very recent arrival.

The early material in volume 3 considers the parts played by earlier scholars in the consideration of European Tertiary successions after the first steps taken by Cuvier and Brongniart in their description of the Paris basin in 1811. Chapters 3 and 4 discuss unconformities and the probability of correlating fossil assemblages belonging to different zoological provinces, and chapters 5 and 6 present Lyell's scheme of Tertiary classification (based on the proportion of living species and genera to extinct) which he had developed with G. P. Deshayes. In 1839, he renamed the Late Pliocene as the Pleistocene. He introduced the term Pleistocene to describe strata in Sicily which had at least 70% of their molluscan fauna as current species. This distinguished it from the older Pliocene epoch, which Lyell originally thought to be the youngest fossil layer. Chapters 7–20 are devoted to marine, freshwater, and volcanic phenomena belonging

to the various divisions of Recent and Tertiary time. Chapters 21 and 22 discuss the denudation of the Weald of Kent and Sussex. Deshayes supplied a 52-page appendix consisting of tables of fossil shells. The appendix was repeated in the second edition of 1833, but was omitted from the third and subsequent editions. Lyell continued to revise the *Principles* for all of his life; it was always a work in progress so the history of geology from 1830 to 1870 is encapsulated in its pages, as well as Lyell's views on the important issues of the day.

volume 3 was dedicated to R. I. Murchison. "When we quitted England together for a tour on the continent, in May, 1828, the first sketch only of my '*Principles of Geology*' was finished. Since that time you have watched the progress of the work with friendly interest, and, as President of the Geological Society, have twice expressed in your Anniversary Addresses, your participation in many of my views." This sets the start of the *Principles* project; the completion was also commented on in volume 3, in the preface. "In the summer of 1831 I made a geological excursion to the volcanic district of the Eifel, and on my return I determined to extend my work to three volumes, the second of which appeared in January, 1832. The last volume has been delayed till now by many interruptions, among which I may mention a tour, in the summer of 1832, up the valley of the Rhine, when I examined the loess (vol. iii, p. 151)."

When volume 1 came out it was reviewed by Poulett Scrope (1830) for the *Quarterly Review*. This was, in some ways, a response by Scrope to Lyell's lengthy discussion in the Review of his book on the *Volcanic Formations of Auvergne*. The Lyell (1827) review was perhaps his first major piece of geological writing; it was the first small step towards the *Principles*.

Lyell wrote to Scrope on 9 November 1830: "Murray ought to send you £70 for the good you have done the review, to say nothing of probable aid to his book. I am going on now with vol.ii. It would sell, even if stupid (which it shall not be), so great is the excitement for and against, which vol.i and your article have together caused." Scrope later acknowledged the receipt of £100.

Charles Darwin wrote in his autobiography:

The investigation of the geology of all the places visited was far more important, as reasoning here comes into play. On first examining a new district nothing can appear more hopeless than the chaos of rocks; but by reading the stratification and nature of the rocks and fossils at many points, always reasoning and predicting what will be found elsewhere, light soon begins to dawn on the district, and the structure of the whole becomes more or less intelligible. I had brought with me the first volume of Lyell's '*Principles of Geology*' which I studied attentively; and the book was of the highest service to me in many ways.

Geology was important to Darwin and his main access to the ideas of geology was via the *Principles*, and of course via his friendship with Lyell himself. At a critical moment in his life, the copy of the *Principles* indicated a way forward, a process of thought, which led eventually to *The Origin of Species*.

Prisoner's Dilemma and Cooperation

Daniel S. Smith
Bristol Medical School: Population Health
Sciences, University of Bristol, Bristol, UK

Synonyms

[Evolution of cooperation](#); [Evolutionary game theory](#); [Social dilemma](#); [Strategies for successful cooperation](#)

Brief Definition

The prisoner's dilemma (PD) is a two-player game where there is a conflict between individual and group interests. Overall, both players do better if they both cooperate, yet each individual player does better if they defect. However, if both players defect, then they do worse than if they both cooperate, hence the dilemma. This deceptively simple game has been used extensively to explore the conditions under which cooperation can evolve.

Introduction

The widespread evidence for cooperation in the natural world is often seen as an evolutionary

puzzle. This is because, all else being equal, it is fitness-enhancing to reap the rewards of others' cooperation without paying any of the costs. In a group of cooperators who freely help anyone else, selfish strategies possess increased fitness relative to cooperative strategies, and consequently spread through the population until only selfish types remain (West et al. 2007). The tragedy of this scenario is that all individuals would be better off (i.e., have greater absolute fitness) if everyone cooperated (Rand and Nowak 2013). However, natural selection is inherently myopic and only concerned with immediate relative fitness differences between phenotypes, hence this rather pessimistic conclusion. Nice guys, it would appear, do indeed finish last.

However, cooperation is widespread throughout the biological world, from aphids and bacteria to yeast and zebra finches. Meerkats teach young group-mates to hunt and handle prey by deweaponizing otherwise dangerous scorpions; bees will aggressively defend threats to their nest even if they sacrifice their own lives in the process; and slime molds, which are otherwise solitary, build communal structures when times are tough where only some individuals get the opportunity to spore and reproduce. Closer to home, our bodies are composed of highly-cooperative agents, with all our somatic cells facing no prospect of reproduction in order to pass on the germline. Even genomes and chromosomes can be thought of as collectives of cooperative individual genes.

Human beings are cooperative creatures *par excellence*, working together to build societies, engage in warfare (even at a high risk of mortality), and help strangers in need. We even extend this cooperation across the species barrier, by looking after pets who appear to give very little back in return. Even invisible deities or abstract ideological concepts frequently receive our cooperation. Given the ubiquity of cooperation, there must be some solution to the rather bleak conclusion that all life is destined toward selfishness. Without cooperation, the genes of our distant ancestors would not have collaborated, complex life would not have evolved, and the biological world would solely consist of short, microscopic,

strands of DNA. Of course, we should not be misled into viewing the widespread cooperation in nature through rose-tinted spectacles; exploitation is also rife in nature, with organisms frequently willing to manipulate, cheat, or deceive others, and this aspect of behavior should not be overlooked. Given this, the widespread cooperation we observe in the biological world must have evolved because these cooperative strategies outcompeted their less-cooperative counterparts. Using the framework of the PD, several such solutions will be discussed below.

First, the term “cooperation” needs to be defined, as different authors and different disciplines have different definitions of what constitutes “cooperation” (and associated terms such as “altruism”). Here, cooperation is defined as “a behaviour that provides a benefit to another individual (recipient), and the evolution of which has been dependent on its beneficial effect for the recipient” (West et al. 2007, p. 662). This includes behaviors which are both “mutually beneficial” (i.e., both the actor and recipient benefit from cooperation) and “altruistic” (i.e., the recipient benefits but the actor pays a cost). These “costs” and “benefits” are measured in terms of individual fitness, rather than short-term gains and losses (e.g., resources), meaning that behavior which is costly in the short term yet fitness-enhancing in the long term (e.g., reciprocity; see below) would be classed as mutually beneficial, rather than altruistic.

This definition also includes the important proviso that said behavior must have “evolved to benefit others,” meaning that behavior which helps others as a by-product of otherwise self-interested behavior does not count as cooperation, as defined here. For instance, imagine a scenario where a group of four organisms are being attacked; if none of the group retaliate, then the whole group perishes, while each individual who does retaliate increases their own probability of dying by 10%, while increasing the probability of group survival by 25%. In this scenario, the best strategy is for individuals to retaliate, regardless of the actions of others, as the costs to retaliation (a 10% increase in mortality risk) are outweighed by the benefits (a 25% decrease in mortality risk).

Thus, even though this retaliatory behavior may seem cooperative as it increases the survival of other group members, the benefits derived by others are an incidental by-product of otherwise self-interested behavior, so this should not be categorized as “cooperation” (Clutton-Brock 2009).

The Prisoner's Dilemma

The prisoner's dilemma (hereafter PD) is one of the most commonly used tools to explore the evolution of cooperation. The PD is an outgrowth of “game theory,” a branch of mathematics originated by John von Neumann and Oskar Morgenstern designed to analyze the best strategies when interacting with others, given different conditions. In its simplest one-shot version, the PD formalizes the scenario outlined above, where cooperation should not evolve. There are two players in the PD, both of which have to decide whether to cooperate or to defect. On average, both players do better if they both cooperate, yet there is always the incentive to defect as the fitness pay-offs are greater. Yet if both defect, both players earn less than if they both cooperated. These situations are known as “social dilemmas” (Rand and Nowak 2013), which pit individual and group interests against one another. The PD is by far the most common of these social dilemmas, but others are also possible (see below).

The canonical example of the PD (and where it gets its name) concerns two prisoners in the following scenario. Two suspected criminals are brought in for questioning regarding a serious crime and taken to separate rooms. The police have enough evidence to convict them of a minor crime, but not enough for conviction of a serious crime. Each prisoner is then offered a bargain and can either cooperate with the other prisoner (keep quiet) or defect (testify that the other prisoner committed the serious crime). The outcomes of these actions depend on the behavior of the other player. If both cooperate and keep quiet, then each gets charged with the minor offence and serves 1 year in jail. If one cooperates and the other defects, then the defector walks

		Player A	
		Cooperate	Defect
Player B	Cooperate	-1 / -1	0 / -10
	Defect	-10 / 0	-5 / -5

Prisoner's Dilemma and Cooperation, Fig. 1 A pay-off matrix for the PD. The behaviors at the top and the side of the matrix reflect the behavioral decisions made by each player (either cooperate or defect). Each cell represents the number of years spent in prison. The pay-offs for player A are shown in the top right of each cell (above the diagonal), while the pay-offs for player B are shown in the bottom left (below the diagonal). For each prisoner, regardless of how their partner acts, the highest pay-off is to defect, even though mutual defection is superior to mutual defection

away free while the cooperator spends 10 years in jail for the serious crime. While if they both defect then they both get 5 years in prison. These sentences (or pay-offs) are displayed in Fig. 1.

In this scenario, defection is the only rational decision. Even though mutual cooperation results in the highest average payoff for both prisoners (1 year in jail), there is always the temptation to defect if your partner cooperates, as then you would not spend any time in prison. Cooperation is therefore a risky decision because if you cooperate but your partner defects, then you spend 10 years in prison. Consequently, regardless of the behavior of your partner, defection is the only rational option: if your partner cooperates, you can do better by defecting; while if your partner defects, the best outcome is to also defect.

For generality, these outcomes can be displayed in an abstract pay-off matrix (Fig. 2a). There are four possible outcomes: Reward (R), where both parties cooperate; Temptation (T), where an individual defects on a cooperating partner; Punishment (P), where both parties defect; and the Sucker's pay-off (S), where an individual cooperates but their partner defects. These

outcomes can be ranked according to their pay-offs: $T > R > P > S$. This ordering of outcomes defines the PD scenario (other orderings of pay-offs are discussed below). In addition, for a PD scenario, two Rewards must be greater than a Temptation plus a Sucker's pay-off ($2 \cdot R > T + S$), otherwise in iterated games repeated turn-taking of Temptation then Sucker's pay-offs would lead to greater pay-offs than repeated mutual cooperation. The "classic" pay-offs for these outcomes are $T = 5$, $R = 3$, $P = 1$, and $S = 0$ (Fig. 2b). This formalizes the conclusion above that, regardless of the behavior of your partner, it is in your best interests to defect (as $T > R$ and $P > S$). As the same holds for the other player, they should also defect, regardless of the behavior of the first partner. In this one-shot situation, defection is an "evolutionary stable strategy" (ESS; Maynard Smith 1982), in that no other strategy can invade a population of defectors.

This situation seems to fit many of our intuitions regarding the fragility of cooperation and the benefits of reaping the rewards of others' cooperation. Take food-sharing among hunter-gatherers; it is always better to be the one who receives food without paying the costs of foraging (in terms of time, energy, or risk of injury), even if this reduces the overall amount of resources brought back into camp. Or take trench warfare during World War I; it is always better to attack first (defect), rather than abstain (cooperate), as the enemy might attack first, even if this increases the risk of mortality for both sides.

The PD can also be extended to an n -person game – the "tragedy of the commons" – where the same conclusion holds. To use an agricultural example, if farmers have cattle which graze on a plot of land, it would be optimal in the long run for individuals to only allow the cattle to graze as much as can be grown back (cooperate). This would mean that resources remain stable over time, sustaining the long-term future of the population. However, if one farmer purchases more cattle and allows them to graze on the land (defect), their short-term material pay-off will be higher than the other farmers. Therefore, other farmers must also obtain extra cattle in order to compete, causing the resources of the pasture to

Prisoner's Dilemma and Cooperation, Fig. 2 Pay-off matrices of the PD. The pay-offs for player A are shown in the top right of each cell (above the diagonal), while the pay-offs for player B are shown in the bottom left (below the diagonal). (a) This matrix displays the abstract pay-off structure in a PD. R = Reward (mutual cooperation); T = Temptation (defecting on a cooperative partner);

S = Sucker's pay-off (cooperating on a partner's defection); and P = Punishment (mutual defection). The ranking of these outcomes for a PD (from best to worst in terms of pay-offs) is: $T > R > P > S$. (b) This matrix displays the "classic" pay-offs applied in a PD. These pay-offs were used in Robert Axelrod's tournament

deplete past sustainable levels. Real-world illustrations of this "tragedy of the commons" abound: overexploitation of natural resources, man-made climate change, and tax avoidance are all obvious examples where short-term individual gain can have damaging long-term population-level consequences. As can be seen from these handful of examples, the PD can be an incredibly useful tool for modeling myriad different social dilemmas which pit individual and group interests against one another.

To summarize, in one-shot games defection is always the best strategy, which is why the evolution of cooperation is often seen as a puzzle. However, given that cooperation is widespread in the natural world, especially among humans, there must be solutions to this rather pessimistic conclusion. In particular, note that the main conclusion of the PD only holds under rather special circumstances: (i) partners will never meet again; (ii) partners are not related; and (iii) partners interact randomly with others in the population (i.e., individuals cannot choose their partners). If these conditions are not met, then cooperation can evolve, despite the short-term benefits of defection. Several such solutions will be discussed below.

Solution 1: Repeated Interactions

In a PD scenario, defection is the only optimal strategy if interactions are not repeated (and players are not related and cannot choose their partners; see sections "Solution 2: Kin Selection" and "Solution 3: Cooperative Assortment"). Clearly, however, in iterated games, the long-term pay-offs to cooperation are greater than the short-term benefits of defection. Imagine a PD with the pay-off structure in Fig. 2b, repeated for 10 rounds with the same partners. Now consider two sequences, X and Y. In sequence X, Player A cooperates first, while Player B defects; player A therefore receives 0 points, while player B receives 5. In sequence Y, both players cooperate, so both receive 3 points. So far, it appears that defectors have greater fitness. However, in sequence X, Player A now defects (as does player B); therefore, from rounds 2 to 10, each player only receives 1 point per round. For sequence Y, in contrast, both players continually cooperate, so earn 3 points per round. Both players in sequence Y earn 30 points, while in sequence X player A receives a total of 9 points, while player B receives a total of 14. Therefore, if the PD is iterated, cooperators can have higher fitness than defectors.

However, in a *finitely* repeated PD, there is a problem. If players know that the game will only last 10 rounds, then they have an incentive to defect on the last round, thereby increasing their overall pay-offs without harming their future interactions with the other player (because there are none). The other player of course also realizes this, so both players are likely to defect on the tenth round. This effectively means that the ninth round of the game becomes the “final” round, as players will expect their partner to defect on the tenth round, which encourages both players to defect in this preceding round. This vicious cycle repeats back until the first round, in which case the game simply returns to a one-shot PD and the only rational choice is to defect (Axelrod 1984).

Repeated interactions may not therefore solve the problem of cooperation unless the game is repeated for an *unknown* length of time (although note that experimental work has shown that even in finitely repeated games, levels of cooperation are sustained for longer than theoretically expected, although defection does increase as the known end-point approaches; Selten and Stoecker 1986). If players do not know when the final round will be, then the above issue does not arise. In this situation, players do not know with certainty when the final round will be, removing the temptation to defect on the final round; therefore, increasing overall levels of cooperation as long as the probability of repeated interactions is sufficiently high. This corresponds to the common-sense notion that it is better to cooperate with someone if you plan to meet them repeatedly in the future, compared to someone you probably will not meet again.

A test of these predictions was formalized in Robert Axelrod's infamous tournament competition, in which various strategies were pitted against one another in an iterated PD game (Axelrod 1984). There were two versions of this tournament. In the first version, 14 game theorists from fields of economics, psychology, political science, mathematics, and sociology submitted strategies which were paired against one another for five games of exactly 200 moves each (with the pay-offs in Fig. 2b). After this first tournament, a second tournament was staged, which

received 62 entries from six countries. In this second tournament, each strategy was paired for five games of varying length, with an average of 151 moves per game. Example strategies submitted to these tournaments include:

RANDOM: This program randomly cooperates and defects with equal frequency.

GRIM: This strategy cooperates until the other player defects, after which GRIM is unforgiving and always defects until the end of the game.

TFT (tit-for-tat): This program simply begins with “cooperate,” then repeats the previous move of its partner (i.e., if its partner defects, TFT will defect on the next round, while if its partner cooperates, so will TFT in the next round).

JOSS: Similar to TFT, but instead of always cooperating when the other player cooperates, 10% of the time JOSS will defect after its partner's cooperation.

TFTT (tit-for-two-tats): This strategy is equivalent to TFT, but rather than defecting after every partner's defection, it will only defect once its partner has defected twice in succession.

TRANQUILIZER: This rule attempts to build up mutually beneficial cooperative relationships with its partner, while also defecting if its partner defects too often. If a cooperative relationship is established, however, TRANQUILIZER attempts an occasional defection to try and exploit its partner, hoping that the partner will forgive the infrequent transgression. If the partner does not retaliate these defections, then the frequency of defections increases.

In both of these tournaments, rather surprisingly the simplest program came out on top: tit-for-tat (TFT). This strategy received the highest overall score in both tournaments and was shown to be robust in additional analyses against different compositions of other strategies. Additionally, in an iterated evolutionary simulation, where the strategies with the highest score in each generation produced more offspring in the next generation, TFT again outperformed all other strategies and left the most descendants. That is, TFT did

well against all manner of opponents, under a wide range of parameters. TFT was able to succeed against other cooperative strategies by reciprocating in kind, while at the same time was effective against “nasty” strategies as it could not be exploited easily (any defections were met by an immediate defection by TFT). More complex strategies which tried to exploit others were less successful as their defections were likely to set off chains of mutual punishment and defection.

In this iterated PD scenario, TFT was found to be an ESS, in that it is able to resist invasion from any other strategy, provided the PD is repeated enough times. This is because no other strategy can receive a greater pay-off – and therefore greater fitness – than TFT in an iterated PD (for additional details and formal proofs, see Axelrod 1984 and Maynard Smith 1982). The pay-off of TFT against itself is repeated mutual cooperation. The pay-off of TFT against any other cooperative strategy will also be sustained mutual cooperation (i.e., CCCC), so this strategy cannot have higher fitness than TFT, so cannot invade. The pay-off of TFT against an alternating strategy (e.g., DCDC) will always be lower than mutual cooperation (as $T + S < 2 \cdot R$), so this strategy cannot invade TFT. Similarly, a strategy of mutual defection (i.e., DDDD) will also have a lower pay-off than mutual cooperation, so also cannot invade. However, it is important to note that other cooperative strategies can do equally as well as TFT, and this point will be returned to below.

Given the success of this simple TFT strategy, from this tournament Axelrod devised four “guidelines” characteristic of successful strategies which are likely to be important in order to promote cooperation:

Be nice: Never be the first to defect. Of the 15 highest-ranked strategies, all but one was “nice,” in that they were never the first to defect (the highest-ranked “nasty” strategy finished eighth). Of the bottom-ranking 15 strategies, all were nasty.

Reciprocate both cooperation and defection: That is, be both retaliatory and forgiving. It is important to be retaliatory so that other strategies do not exploit you. TFT does this well by

punishing any defectors immediately. At the same time, it pays to be forgiving. If another player defects but then tries to cooperate afterward, it is better to forgive them and cooperate in the future rather than risk repeated mutual defection. It is this quality that enabled TFT to perform better in the tournament than GRIM (which never forgave an initial defection by its partner).

Don't be envious: Successful cooperation is not about obtaining a higher score than your opponent. A striking (although obvious, given some thought) fact is that TFT never beat any of its opponents; the best it could do was to draw (i.e., mutual cooperation), but in the process both partners could accrue a high score. Strategies which tried to beat their opponents were more likely to end up in cycles of defection and consequently earn lower scores.

Be clear: Don't be too clever. TFT is a simple strategy to understand, while more complex programs are difficult to figure out and therefore predict their behavior (such as TRANQUILIZER). For cooperation to be sustained, clarity is key.

This tournament highlights the importance of reciprocity and repeated interactions for the evolution of cooperation, supporting the conclusions presented a decade earlier by Robert Trivers (1971). However, despite the success of TFT, it is not an ESS under all circumstances. Firstly, in a population of ALLD (always defect), a lone TFT cannot succeed as there are no other cooperative strategies to interact with. Therefore, assuming that the mutation rate is not too high and that cooperative strategies enter the population one at a time, defectors will always have higher fitness (Axelrod 1984). As a concrete example, given five rounds of an iterated PD, a solitary TFT will only earn four points (TFT is a sucker once, then defects), while its ALLD partner will earn nine points. All other ALLD strategies in the population which only play against one another earn five points each. ALLD is therefore also an ESS, although TFT has a much wider basin of attraction once cooperative strategies have gained a foothold in the population. TFT therefore has trouble

explaining the initial evolution of cooperation from a noncooperative population, but it can explain its maintenance and spread once cooperation has crossed a certain threshold. However, from a population of defectors, cooperation can evolve if two cooperative strategies emerge at the same time and preferentially cooperate with one another (cooperative assortment; see section “[Solution 3: Cooperative Assortment](#)”), or if the two players are related (kin selection; see section “[Solution 2: Kin Selection](#)”).

Secondly, if there is “noise” in the model, either in terms of mutation and drift or mistakes by other players (e.g., a cooperative strategy may accidentally defect), then TFT is not necessarily an ESS. In a population of TFT, the pay-offs for TFT and other cooperative strategies are equivalent, meaning that given some mutation rate other strategies can invade by genetic drift (Nowak and Sigmund 1993). For instance, if ALLC (always cooperate) invades a population of TFT by drift, this will then trigger further evolutionary dynamics as “nasty” strategies can exploit ALLC. Additionally, Axelrod’s tournament is predicated on the assumption that strategies never make mistakes. This is clearly not the case in the real world as organisms may misinterpret or forget the behavior of their partner and subsequently defect when they should have cooperated. Indeed, after Axelrod’s tournament, it was found that TFT may not be the “best” strategy, as PAVLOV (or, “win-stay, lose-shift”) was found to do better than TFT if mutation and occasional mistakes were included in the model. PAVLOV simply repeats its own previous behavior if it wins (R or T pay-offs), while shifts to the alternative strategy if it loses (P or S pay-offs). PAVLOV’s success over TFT can be attributed to two factors. Firstly, it can exploit unconditional cooperators, while TFT only engages in mutual cooperation with these partners. This means that PAVLOV cannot be invaded by unconditionally cooperative strategies due to drift, unlike TFT. Secondly, PAVLOV can correct occasional mistakes, while for TFT any defection – even accidental – can result in repeated bouts of retaliation. There is therefore no single “best” rule in an iterated PD, independent of the environment of other strategies, but

rules such as TFT and PAVLOV do appear to be robust under a wide range of conditions.

Thirdly, these conclusions only hold in a simultaneous PD game, where both players make their decisions at the same time. While this situation may correspond to some types of cooperative behavior, other situations may reflect an “alternating” PD, where individuals take it in turn to decide whether to cooperate or not (Nowak and Sigmund 1994). For instance, bird parents often take turns obtaining food for their young, while bouts of animal grooming are generally alternating, as are food-sharing situations in human and nonhuman animals. TFT may not be the best strategy in these scenarios, especially if reciprocation is not immediate and there are disparities in need. Need is important as the value of receiving cooperation is greater for those in need compared to those with an abundance of resources (Trivers 1971). Take a monetary example; \$1,000 is more valuable to a person in poverty than to a millionaire. Similarly, the costs to sharing are greater for individuals in need compared to individuals with lots of resources. Using the \$1,000 example again, the cost of sharing this amount is obviously greater to the person in poverty compared to the millionaire. Many PD scenarios assume that the pay-offs are equivalent between the two players, yet these value asymmetries greatly change the cooperative dynamics, making cooperation more likely to evolve (Trivers 1971). For instance, in hunter-gatherer societies, a small number of highly-productive individuals tend to provision others much more than they receive in return. Although this behavior appears altruistic, the costs to sharing these resources are low, relative to the benefits to the needy individuals receiving the food. Importantly, when the tables are turned and these productive cooperative individuals find themselves in need, due to illness or injury, they are more likely to receive resources than less-productive foragers (Gurven et al. 2000). Similarly, among the Agta, a Filipino hunter-gatherer population, individuals in need were both less likely to share resources (Smith et al. 2016) and more likely to receive resources from others (Smith et al. 2018). Such need-based sharing may reflect reciprocal cooperation, but in

circumstances beyond those modeled by simultaneous PD games such as Axelrod's tournament.

Nonetheless, despite these caveats regarding TFT, the basic conclusion that reciprocity and nice strategies can facilitate the evolution of cooperation has been repeatedly supported, both theoretically (see above) and empirically. As a few additional case studies: repeated economic games in a lab are associated with greater levels of cooperation (Rand and Nowak 2013); stable hunter-gatherer camps with a high probability of repeated interactions are more cooperative than camps with a high turnover in membership (Smith et al. 2016); and truces in trench warfare in World War I were more probable when troops were stationed opposite one another for longer lengths of time (Axelrod 1984).

Solution 2: Kin Selection

The paradox of the PD can therefore be overcome by repeated reciprocal interactions. A further solution is through cooperating with those who you share genes with, meaning that by helping relatives you can indirectly pass on your own genes to future generations. Although evolutionary geneticists such as Sewall Wright and JBS Haldane had an intuitive understanding that shared ancestry was important in explaining cooperative behavior, this approach was formalized by William Hamilton (1964) with his theory of "inclusive fitness," often referred to as "kin selection." Hamilton demonstrated that genes for altruism could propagate through a population if these altruistic acts were directed toward genetic relatives. Thus, even though these altruistic acts harm the individual's own fitness (known as their "direct fitness"), they can still evolve if it increases their inclusive fitness by increasing the fitness of their relatives (an individual's "indirect fitness").

The likelihood of an altruistic trait spreading through the population depends on three factors: (i) the benefit to the individual receiving the altruistic act (b), in terms of lifetime reproductive success; (ii) the cost of the actor performing said altruistic act (c), in terms of lifetime reproductive success; and (iii) the coefficient of relatedness between the actor and the recipient (r), which is a measure of assortativity based on genetic

relatedness. If $r = 0$, then kin who share a trait are no more likely to interact with one another than randomly selected members of the population. As r increases, kin are more likely to interact with their genetic relatives (i.e., those who share the same trait), and less likely to interact with nonrelatives (i.e., those who do not share the trait). r frequently (although not always; West et al. 2007) reflects the proportion of genes shared by common ancestry (e.g., 0.5 for parents/offspring/full siblings, 0.25 for aunts/uncles/nieces/nephews, 0.125 for cousins, and so on). Altruism is therefore expected if the benefits to the recipient of a cooperative act, as a function of relatedness, outweigh the cost of the action. This is known as Hamilton's Rule, as is given by the simple formula: $br > c$. To take a simple example, if the cost of an altruistic act is a one-unit reduction in reproductive success for the actor, but a three-unit increase for the recipient, the actor is likely to cooperate if the recipient is a full sibling, but not a niece or nephew. This is because, for a full sibling, 3 (the benefit to the recipient) times 0.5 (relatedness between siblings) is 1.5, which is larger than 1 (the cost to the actor), so the benefits outweigh the costs. For a niece or nephew, however, the benefit is 3 times 0.25 (0.75), which is lower than the cost to the actor, so cooperation would not be expected to evolve in this instance.

As a more formal example, imagine a one-shot PD where $c = 1$ and $b = 3$, meaning that cooperative individuals give up one unit of fitness to increase the fitness of their partner by three units. Defectors pay no costs and help no one. Assuming that all individuals have a baseline unit of fitness (to avoid negative fitness outcomes), the PD pay-offs are: $T = 1 + b = 4$; $R = 1 + (b - c) = 3$; $P = 1 + 0 = 1$; $S = 1 + (-c) = 0$. If we assume random assortment (i.e., $r = 0$), then the inclusive fitness of cooperators is $1 + br - c = 1 + (3 \cdot 0) - 1 = 0$, while the inclusive fitness of defectors is just 1 (their baseline fitness). Given random assortment, defectors have higher inclusive fitness than cooperators. However, when individuals preferentially interact with kin (say, $r = 0.5$), then cooperators have higher inclusive fitness than selfish types, as now the inclusive fitness of cooperators is $1 + br - c = 1 + (3 \cdot 0.5) -$

1 = 1.5, while the inclusive fitness of defectors is still just 1 (their baseline fitness). Note also that from an inclusive fitness perspective the help received from others is ignored, as only the impact of the focal individual's behavior on themselves (c) and others (b , weighted by r) is counted.

Things become slightly more complicated from an inclusive fitness perspective when dealing with nonadditive pay-offs, meaning that the PD pay-off matrix cannot be described solely in terms of c and b . Take the matrix in Fig. 2b, where $T = 5$, $R = 3$, $P = 1$ and $S = 0$. To model this (again assuming a baseline unit of fitness): $T = 1 + b$; $R = 1 + (b - c + d)$; $P = 1 + 0$; $S = 1 + (-c)$, where $b = 4$, $c = 1$ and $d = -1$. Now a "synergistic" d term must be added to the Reward pay-off to satisfy the pay-off matrix. This addition makes deriving a simple " $br > c$ " type inequality – which partitions fitness into direct fitness (c) and indirect fitness (br) – more complicated, although not impossible (see Gardner et al. 2011).

A simpler method to model whether cooperation will evolve among kin when pay-offs are non-additive is to use the "personal fitness," rather than inclusive fitness, approach (also known as "neighbor-modulated fitness"). Personal fitness is calculated based on an individual's total reproductive success (i.e., costs to self of performing the cooperative behavior plus the help received from interacting with cooperative partners). This is in contrast to the inclusive fitness approach where fitness is based on the cost to self of performing the cooperative behavior plus the help given to others, weighted by relatedness. From this personal fitness perspective, the average fitness of each strategy is simply the pay-offs (R and S for cooperators; T and P for defectors), multiplied by the probability of different strategies interacting, which is determined by both r and the frequency of cooperators and defectors in the population (Maynard Smith 1982). Using this personal fitness approach, cooperators can invade a population of defectors if: $rR + (1-r)S > P$. P is the expected fitness of defectors (given that the population is composed primarily of defectors, defectors interact with cooperators so infrequently that the T pay-off is practically 0 so

can be ignored), rR is the pay-off to a cooperator meeting another cooperator (R) multiplied by the probability of a cooperator meeting another cooperator (r), while $(1-r)S$ is the pay-off to a cooperator meeting a defector (S) multiplied by the probability of a cooperator meeting a defector ($1-r$). By the same logic, defectors can invade a population of cooperators if: $rP + (1-r)T > C$. Therefore, given the PD matrix in Fig. 2b, cooperators can invade a population of defectors when $r = 0.5$, as $0.5*3 + (1-0.5)*0 = 1.5$, which is greater than P (1), while a population of cooperators can resist invasion by defectors, as $0.5*1 + (1-0.5)*5 = 3$, which is not greater than R (3). Note also that given the pay-offs in Fig. 2b, one-shot cooperation cannot evolve if $r < 0.33$, while a stable polymorphism of cooperators and selfish types will co-exist given values of $r < 0.5$ and $r > 0.33$.

Supporting these theoretical predictions, kin selection is a powerful explanation for the existence of cooperation in nature, with much seemingly altruistic behavior explicable in terms of increasing an organism's inclusive fitness, even if it damages their direct fitness (West et al. 2007). Organisms caring for their siblings, self-sacrifice in eusocial insects, somatic cells working in service for the germline, and numerous other examples highlight the importance of kin selection in explaining cooperative behavior. Although it can be difficult to dissociate indirect and direct fitness benefits in humans – e.g., we often reciprocally cooperate with our relatives (Rand and Nowak 2013) – kin selection appears to be a powerful force shaping human affairs: kin-based nepotism is rife in human societies, including inheritance rules and regal succession; fictive kinship terms, such as "brother" or "sister," are applied to non-kin as a sign of friendship; while food-sharing among foragers is often targeted toward kin, even when controlling for reciprocal sharing (Smith et al. 2016). Thus, kin selection demonstrates how relatedness can promote the evolution of cooperation, even in one-shot interactions.

Solution 3: Cooperative Assortment

The pessimistic conclusion of the PD also only holds in a well-mixed population, where

cooperators cannot choose who they interact with. If, however, organisms can “rig the game” and only interact and cooperate with other cooperative organisms, then cooperation can evolve much more readily. The previous two solutions above can also be thought of as solving the dilemma via similar assortative processes; repeated cooperative interactions with the same individual, rather than interacting randomly with the population (reciprocity; see section “[Solution 1: Repeated Interactions](#)”) and interacting with close kin, as opposed to nonrelatives (kin selection; see section “[Solution 2: Kin Selection](#)”). At a fundamental level, cooperation can evolve if there is positive assortment in cooperative phenotypes; in the words of William Hamilton, “kinship should be considered just one way of getting positive regression of genotype in the recipient, and that it is this positive regression that is vitally necessary for altruism. . . . it obviously makes no difference if altruists settle with altruists because they are related (perhaps never having parted from them) or because they recognize fellow altruists as such, or settle together because of some pleiotropic effect of the gene on habitat preference” (Hamilton 1975, p. 337). Thus, all theories for the evolution of cooperation are predicated on the principle of assortment.

However, while reciprocity and kin selection are theories of assortativity, they are not theories of *cooperative* assortativity as they do not require organisms to cooperate with others based solely on their partner’s level of cooperativeness. As will be described below, theories of cooperative assortativity can help explain the otherwise seemingly inexplicable cooperation between nonrelatives who may not interact again in the future. This type of cooperation is seen routinely in modern market-based economies, including giving to charity, volunteering, purchasing goods, and academic peer review.

At its most basic level, cooperative assortment occurs when cooperative phenotypes preferentially interact with other cooperative phenotypes. This is easier said than done, however, as mechanisms to establish and maintain this cooperative assortment are required to keep defectors at bay. The concept of “partner choice” is relevant here,

especially when compared to so-called “partner control” (Barclay 2013). Partner choice occurs when individuals can choose who to cooperate with (or to “walk away” from noncooperators), while under situations of partner control individuals cannot avoid noncooperators, but rather have to control the effects of their partner’s selfish behavior. In a repeated PD scenario like Axelrod’s tournament, partners cannot choose each other, so strategies which limit exploitative partners by conditional cooperation and punishment, such as TFT, are necessary; this is an example of a “partner control” situation. On the other hand, if individuals could choose their partners, or walk away from them when they wished, this would constitute a “partner choice” situation. Therefore, if individuals can avoid uncooperative others, rather than having to control them, cooperation can evolve more readily, even in one-shot interactions (Rand and Nowak 2013; Roberts 2015).

One method to promote this cooperative assortment is through the use of reputation. Indirect reciprocity is one such mechanism, which is based on the principle of “helping those who help others” (Nowak and Sigmund 1998). If individuals acquire a reputation for cooperation by being cooperative, and this reputation is known by others, those with a reputation for cooperation are more likely to be cooperated with, irrespective of a lack of previous encounters. Theoretical models have indicated that cooperation can evolve via this process (Nowak and Sigmund 1998), especially when combined with mechanisms of partner choice to avoid uncooperative individuals (Roberts 2015). Results from several empirical studies (reviewed in Milinski 2016) have found results consistent with indirect reciprocity. For example, noncooperative individuals are less likely to be cooperated with in the future, while individuals also appear to engage in “reputation management”; if their behavior will be made public to others, they are more likely to cooperate. Such behavior is particularly apparent in online marketplaces, such as eBay, where individuals who cultivate a reputation for outstanding customer service are more likely to attract new customers.

A related theory based on reputation and cooperative assortment is “competitive altruism” (also

known as “reputation-based partner choice”; Sylwester and Roberts 2013). According to this theory, individuals first signal their cooperativeness, after which these cooperative individuals are more likely to be chosen for mutually beneficial cooperative ventures. For instance, a forager may share their food widely with the camp in order to subsequently be chosen as a partner to share food with or to be chosen as a cooperative hunting partner. Although reputation-based partner choice and indirect reciprocity make similar predictions, such that seemingly costly displays of cooperation will be rewarded by cooperation in future encounters, the mechanisms are distinct. In reputation-based partner choice, individuals preferentially interact with cooperative individuals for future mutually beneficial cooperative interactions with said cooperator. In contrast, indirect reciprocity assumes that individuals help cooperative others solely to enhance their own cooperative reputation so that others will cooperate with them, irrespective of future mutually beneficial interactions with the same partner. Nonetheless, both are theories of cooperative assortment which can explain how one-shot cooperation among non-kin can evolve.

Theories of cooperative assortment are likely to have great relevance in understanding cooperation in modern market-based economies where much cooperation is between unrelated individuals and interactions may not be repeated. Note, however, that these theories based on cooperative assortment may not necessarily predict patterns of cooperation in small-scale societies, where cues other than cooperativeness, such as relatedness or reciprocity, can be used to select partners. For instance, among Agta hunter-gatherers, individuals were more likely to share with *less* cooperative camp-mates, potentially reflecting need-based sharing or the avoidance of being indebted to others. Instead, they were found to preferentially share with kin, reciprocal partners, and those in need (Smith et al. 2018).

Solution 4: Communication and Coordination

Communication and coordination between players does not change the logic of the PD in one-shot games. However, simply giving

strangers 30 min to interact before playing a one-shot PD is enough for participants to predict how cooperative their partner would be (Frank et al. 1993). This simple result highlights the importance of communication and coordination in shaping cooperative behavior. This is especially likely to be a factor in repeated games as individuals need to know that their partner will also cooperate. Unlike the “free-rider problem,” in iterated games, there is a “problem of coordination,” as the issue is not necessarily that of free riders having increased fitness relative to cooperators, but rather the difficulty in coordinating behavior for mutual benefit. In these situations, cooperation may be the best strategy for all parties, yet cooperation may not occur due to a lack of common knowledge over how others will behave.

The iterated PD can be thought of as a coordination game; individuals do best in repeated cooperative interactions, but in order to reap this benefit, they need to know that their partner will actually cooperate. These problems require “meta-knowledge” to solve. Put another way, the important point is not whether an individual knows that cooperation is the best course of action, but whether said individual knows that their partner also knows that cooperation is the best course of action and will act accordingly. Communication is therefore necessary to solve these problems of coordination, and numerous studies have shown that simply allowing players to communicate can promote cooperation (reviewed in Smith 2010).

These coordination games can be modeled in an abstract pay-off structure (Fig. 3), similar to the PD. In these scenarios, defection is not the optimal strategy, as the highest pay-off in these games is achieved by partners coordinating their behavior for mutual benefit (R). As a hypothetical example, imagine two hunter-gatherers having the option of either cooperating to hunt stag or foraging for berries by themselves (the equivalent of defecting in this scenario): If both individuals cooperate, then they are likely to successfully hunt a stag, which is a big haul for both partners (a pay-off of 5 each); if both players decide to forage individually for berries, then both receive a lower amount

		Player A	
		Cooperate	Defect
Player B	Cooperate	5 / 5	2 / 0
	Defect	0 / 2	1 / 1

Prisoner's Dilemma and Cooperation, Fig. 3 An example of a coordination game pay-off matrix. Here, in order to reap the most rewards, players need to coordinate their behavior. The pay-offs displayed here reflect a “stag-hunt” scenario (see text) where the player who cooperates does worse than the one who defects ($R > T > P > S$), although other coordination games exist where any non-matching behavior is inferior to mutual defection, in which case $R > P > T = S$. The pay-offs for player A are shown in the top right of each cell (above the diagonal), while the pay-offs for player B are shown in the bottom left (below the diagonal)

of food (a pay-off of 1 each); however, if an individual decides to hunt stag and their partner decides to pick berries, then the berry-picker still receives some resources (a pay-off of 2), while the stag-hunter has no chance of a successful hunt by themselves, so receives a pay-off of 0. Therefore, in order to reap the rewards of cooperation, individuals need to coordinate their behavior.

One real-world example of such a coordination game involves foraging strategies among the Lamalera from Indonesia (Alvard and Nolin 2002). In this society, individuals can either fish individually or collectively hunt whale (which has a greater pay-off than solitary fishing). In order to coordinate behavior and ensure that cooperation (collective whale hunting) is profitable for all involved, complex sets of social norms exist among the Lamalerans, including specific rules over distributing whale meat. These social norms ensure that all Lamalerans are aware of the “rules of the game,” thereby coordinating their behavior for mutual benefit. While language obviously serves this purpose of coordinating social behavior (Smith 2010), storytelling may be another such mechanism to broadcast this meta-knowledge,

therefore promoting cooperation (Smith et al. 2017). A large proportion of stories told in hunter-gatherer societies appear to concern social behavior, particularly regarding extolling the virtues of prosocial behavior (such as cooperation and equality) and the punishment meted-out to norm violators (such as selfish or lazy individuals). These stories also appear to enhance cooperation, as among the Agta (a Filipino hunter-gatherer population mentioned earlier) higher levels of cooperation in an experimental game were associated with a greater proportion of skilled storytellers in camp. Thus, the importance of mechanisms to coordinate behavior for mutual benefit should not be overlooked when exploring the evolution of cooperation.

Multilevel Selection and the Evolution of Cooperation

This chapter has focused on an “inclusive fitness” approach to understanding cooperative evolution (Hamilton 1964; West et al. 2007). An alternative conceptualization to understanding the evolution of cooperation is through “multilevel selection” (MLS; Hamilton 1975; Sober and Wilson 1998). MLS decomposes fitness into a “between-group” component and a “within-group” component (if the population is not structured into groups, then the between-group component is absent). Selection favors selfish behavior within groups (because altruists have lower fitness than selfish types within groups), while selection favors altruistic behavior between groups (because groups with altruists have greater fitness than groups with fewer or no altruists). If between-group selection outweighs within-group selection, then seemingly altruistic behavior can spread through the population.

However, there are two important points to note here. Firstly, MLS models are mathematically equivalent to inclusive fitness models; the only difference is how they decompose fitness. MLS decomposes fitness into within-group and between-group components, while inclusive fitness decomposes fitness into direct and indirect fitness components. From an inclusive fitness

perspective, the consequences of between-group interactions are part of an individual's inclusive fitness. Secondly, the MLS definition of altruism is different to the inclusive fitness definition of altruism. Altruism in an MLS framework is a behavior which lowers an individual's fitness within a group, regardless of the between-group benefits to cooperation (Sober and Wilson 1998). Altruism from an inclusive fitness perspective, as described above, is a behavior which decreases an individual's direct fitness, so can only evolve if cooperation increases an individual's indirect fitness (Hamilton 1964; West et al. 2007). It is important not to confuse the two: behavior may be altruistic from an MLS perspective, but not altruistic from an inclusive fitness perspective.

An example may make these points a little less abstract. Take between-group conflict. Imagine two groups in conflict over a limited resource (land, say), and individuals in each group can either cooperate (help in the conflict at a cost to self, relative to group-mates) or defect (not participate, so pay no cost, but reap the rewards of their group-mates' cooperation). From an MLS perspective, cooperative individuals obviously have lower fitness than selfish individuals within groups, so this behavior is altruistic (as defined by MLS). However, groups with more cooperators are more successful in between-group conflict, so cooperative behavior may spread in the population if the strength of between-group selection is great enough.

From an inclusive fitness perspective, however, if groups are composed of kin, then this cooperative behavior can be understood in terms of individuals maximizing their inclusive fitness by increasing their indirect fitness, even at a cost to their direct fitness. This behavior is therefore still altruistic, but this time from an inclusive fitness perspective. Alternatively, if groups are not composed of kin, then this cooperative behavior can still be understood from an inclusive fitness standpoint as individual fitness also depends on group fitness (i.e., individuals from cooperative groups have greater fitness than individuals from less cooperative groups). Cooperative individuals may therefore increase their direct fitness

by being part of a cooperative and successful group, even if said group contains some defectors who have even greater fitness than themselves. This behavior would therefore be altruistic from an MLS perspective, but not altruistic from an inclusive fitness perspective.

Each of the processes described above as solutions to the PD – repeated interactions, kin selection, and cooperative assortativity – can be described in a multilevel, as opposed to an inclusive fitness, framework (Sober and Wilson 1998). In each case, groups of cooperators propagate, even though individual cooperators have lower fitness than defectors within groups. However, it is essential to remember that MLS is not an alternative process to inclusive fitness, but rather is simply a different perspective on the evolutionary process and an alternative way of doing the math. The perspective one chooses to adopt will depend on the specifics of the system being studied: if groups act predominantly as unified wholes (such as whole organisms or, potentially, eusocial insect colonies), then an MLS perspective may be fruitful; if populations are not structured, then an inclusive fitness approach will be more appropriate; for cases in-between – where populations are structured into groups, but these groups do not act as unified wholes (such as human groups) – then it may be a matter of personal preference which perspective to adopt.

Limitations of the PD for Understanding Cooperation

While the PD has undoubtedly been a valuable tool for understanding the evolution of cooperation, it does possess some limitations. Firstly, not all cooperative behavior can be modeled as a PD. As discussed above, many cooperative situations resemble coordination game scenarios (Fig. 3), which do not suffer from the free-rider problem but rather suffer from problems of coordination. An alternative scenario, although still a social dilemma, is known as the “snowdrift game.” Imagine a situation where two drivers are stuck behind a snowdrift; as with the PD, individuals can either cooperate (dig through the

snowdrift) or defect (not dig). While joint cooperation would mean clearing the snow faster, defecting and letting the other dig would be a superior strategy as no energy would be expended. However, in this case, being the “sucker” (the individual who cooperates while the other defects) is superior to mutual defection, as they still benefit by clearing the snow and getting home. The pay-off structure for this scenario is therefore $T > R > S > P$ (Fig. 4). In the snowdrift game, defection is not the optimal strategy in one-shot interactions, resulting in a mixed population of cooperators and defectors (Doebeli and Hauert 2005). Accordingly, experimental findings have indicated that levels of cooperation are greater in an iterated snowdrift game compared to an iterated PD game (Kümmerli et al. 2007). Note also that this game is formally identical to the “Hawk-Dove” game (Maynard Smith 1982) or to the common childhood game of “chicken” (where the first to “blink” – or “chicken out” – is the cooperator).

When “cooperating” in this snowdrift game situation, the benefit to the partner may be incidental, meaning that behavior in these situations

		Player A	
		Cooperate	Defect
Player B	Cooperate	3 / 3	5 / 1
	Defect	1 / 5	0 / 0

Prisoner's Dilemma and Cooperation, Fig. 4 The pay-off matrix for a snowdrift scenario. As with the PD (Fig. 2), the Temptation pay-off is superior to mutual cooperation (Reward). However, in contrast to the PD, mutual defection (Punishment) is inferior to being the Sucker. The ranking of these outcomes for a snowdrift scenario (from best to worst, in terms of pay-offs) are: $T > R > S > P$. The pay-offs for player A are shown in the top right of each cell (above the diagonal), while the pay-offs for player B are shown in the bottom left (below the diagonal)

may not be strictly cooperative, but rather reflects self-interest (Clutton-Brock 2009; West et al. 2007). That is, players cooperate (dig through the snowdrift) in order to get themselves home because that is preferable to being stuck behind the snowdrift; the benefit to the other player is wholly incidental. Although cooperation in this scenario benefits others, it did not evolve to do so as the effect on the other player is an unintended by-product.

The snowdrift game appears to characterize several real-world circumstances, particularly regarding “producer-scuronger” dynamics. In these situations, some organisms produce resources, such as food, information, or cultural knowledge, which is then appropriated – or “scrounged” – by others in the group. To take a foraging example, while neither party may wish to forage and have food taken by others, the costs to not foraging are greater for some individuals. These individuals would therefore “blink” first in this game of chicken. For instance, compare an individual with multiple dependent offspring against another individual with no dependents. In this scenario, the second childless individual has less need to forage compared to the first as the costs to not foraging for the individual with multiple children are larger as their household is in greater need of resources. Consistent with this idea, men from Ifaluk atoll with more dependent offspring were more likely to fish compared to those with few dependents, as the costs to not foraging were greater for those with many mouths to feed (Sosis et al. 1998). These alternative pay-off structures have been under-researched compared to PD scenarios, despite their seeming applicability to several kinds of social interactions among a number of taxa (Alvard and Nolin 2002; Clutton-Brock 2009; Doebeli and Hauert 2005).

In addition to their theoretical utility, the PD and associated games, such as the Public Goods Game, Ultimatum Game, and Dictator Game, have been used extensively in experimental settings to empirically assess behavior in social dilemma scenarios (Camerer 2003). Although these experimental protocols offer conceptual simplicity and clarity, in practice there are many difficulties in interpreting behavior in these

games. Foremost among these are concerns over the ecological validity and interpretation of such experimental results.

Taking issues of external validity first, it is often not clear how, or even whether, behavior in these games reflects real-world cooperation. In these experimental games, initial levels of cooperation are generally quite high; in Public Goods Games players tend to share half of their endowment, while in Dictator Game situations (where individuals simply share some proportion of resources with an unknown recipient), individuals still often offer around 20% of the stake, despite no threat of punishment or future interactions (Camerer 2003). However, in the real world, such cooperative behavior is generally not observed; a recent field study based in Las Vegas found that individuals given a windfall of resources (casino chips) at a bus stop shared none of the chips with another individual waiting nearby, even after being instructed that they could share them with the other person if they wanted (Winking and Mizer 2013).

Additionally, there are difficulties concerning whether behavior in these experimental games reflects a single, stable, cooperative construct. For instance, it is not clear whether cooperation is a unitary phenomenon – and therefore stable from one context to the next – or whether it is more context-dependent – in which case experimental cooperation may not reflect real-world cooperation or cooperation in a different experimental game. Although some studies have attempted to overcome these criticisms, by demonstrating that game behavior predicts real-world cooperation and that cooperation in one context predicts cooperation in a different context (e.g., Peysakhovich et al. 2014), interpretation over the validity of these games is an area of active research and debate.

Conclusion

The PD has been widely used as a theoretical and empirical tool to explore the circumstances under which cooperation is likely to evolve. As of

August 2018, a Scopus search for the term “prisoner’s dilemma” in titles, abstracts, and keywords returned over 5,000 articles. It is likely that this fascination with this seemingly simple yet beguiling game will continue for years to come, offering insights into why humans and other animals both cooperate extensively with each other yet simultaneously aim to exploit one another when possible. The PD is an intuitive and fundamental insight into social behavior and the conflict between selfish and cooperative strategies; the dilemma is unlikely to be solved any time soon.

Prisoner's Dilemma Outcomes

Lindsay Chassay

Kansas State University, Manhattan, KS, USA

Alliances; Being a sucker; Betrayal; Collusion; Noncooperation; Temptation

Definition

When two individuals are interacting, and their behaviors reward them in ways that depend on both their own actions and the actions of the other individual, one scenario that can occur is the “prisoner’s dilemma.” Four outcomes are possible in a prisoner’s dilemma: mutual cooperation (both parties cooperate), mutual defection (both parties’ defect), a sucker’s payoff (received by an individual who cooperates when the other player defects), and a temptation payoff (received by an individual who defects when the other player cooperates).

Introduction

How people interact with one another can involve a wide range of behaviors, intentions, and outcomes. There is a long history of philosophical positions about the fundamental nature of human interactions, including whether the nature of these interactions is fundamentally benevolent (e.g., Rousseau 1762), fundamentally aggressive (e.g., Hobbes 1651), or some combination thereof. As ideas about the nature of human interactions moved away from such a strict dichotomy and recognized the importance of context, other ways of characterizing human social interactions emerged. One approach, known as game theory, addresses how people interact with one another by simplifying the properties of those interactions to their most basic elements. Actors within a game play out strategies such that behavior can be cooperative or antagonistic depending on the costs and benefits of the situation (the payoffs). That is, the actions of one party have a direct effect, either positive or negative, on the outcome of others. Additionally, actors in a game can adjust their own strategies based on previous actions of other parties. For example, an actor who was previously disadvantaged by another player could choose to act antagonistically towards that player, or vice versa (Von Neumann and Morgenstern 1944).

Within game theory, one of the most well-known paradigms, or “games,” is called the prisoner’s dilemma. The prisoner’s dilemma

		Player 2	
		Cooperate	Defect
Player 1	Cooperate	-2, -2	-10, 4
	Defect	4, -10	-6, -6

Prisoner’s Dilemma Outcomes, Fig. 1 Typical payoffs in a prisoner’s dilemma. Within each cell, the first payoff is for Player 1 and the second payoff is for Player 2. The blue-highlighted cell (top left) is the outcome of mutual cooperation, and the green-highlighted cell (bottom right) is the outcome of mutual defection. The orange-highlighted cell is the sucker’s pay off for player 2 and the yellow is temptation to defect for player 1, whereas those titles are reversed for the other player in those same cells

demonstrates why two completely rational individuals might not cooperate, even if it appears that it is in their best interests to do so. Formally, the prisoner’s dilemma involves two actors who each have a choice to either cooperate with or defect (not cooperate) from each other. The payoffs for these choices (see Fig. 1) are such that each actor would: (1) benefit the most from defecting when the other player cooperates (often called “temptation”); (2) benefit less from mutual cooperation; (3) benefit even less from mutual defection; and (4) benefit least from cooperating when the other player defects (often called the “sucker’s payoff”).

The individual choice of defection is the dominant choice in this version of the prisoner’s dilemma (i.e., the best outcome of temptation can occur, and the worst outcome of a sucker’s payoff is avoided for each party). However, if both parties in this situation understand the payoffs and choose defection, the result is the relatively unappealing outcome of mutual defection (−6/−6). Paradoxically, both people would almost certainly have preferred the mutual cooperation outcome (−2/−2), but that option seems to be unattainable because each player would assume the other player will rationally choose to defect.

Prisoner Dilemma Scenarios in the Repeated Prisoner’s Dilemma

The above prisoner’s dilemma is called a one-shot, or noniterated, situation because each player is allowed only one chance to cooperate or defect. In principle, cooperation should not occur

because both players have stronger incentives to defect. By not cooperating, however, both people come out worse than if they had worked together (mutual cooperation), hence the dilemma.

The prisoner's dilemma changes in important ways if it is a repeated, or iterated, situation. With multiple rounds of interaction, each player can use strategies that incorporate the other player's previous behaviors. One of the most well-known of the strategies for a repeated prisoner's dilemma is "tit for tat" (TFT), which uses a first move of cooperation but then all subsequent behaviors are based on copying the behavior of the other player during the previous iteration. Under many situations, the tit-for-tat strategy can generate stable mutual cooperation (Axelrod and Hamilton 1981).

Mutual Cooperation/Mutual Defection

These outcomes happen when both players either cooperate or both players defect. Mutual defection gives the worse outcome for both players. The existence of situations and strategies that can lead to mutual cooperation has been a long-standing focus of research with the prisoner's dilemma, because it is often seen as a way to potentially structure real-world environments in such a way that people will adopt cooperative rather than exploitative strategies. For a given environment, Axelrod (1984) offers four tips to foster mutual cooperation: (1) do not be envious; (2) do not be the first to defect; (3) reciprocate cooperation and defection; and (4) do not be too clever. For example, "tit for tat" (TFT) uses a simple algorithm to achieve these tips, whereas being too clever can reduce the clarity of your strategy, confuse the other player, and hinder willingness to cooperate.

Sucker's Payoff and Temptation to Defect

The sucker's payoff and temptation to defect payoff are inverses of each other, so the roles of the two players are inverses of each other. The defecting person is therefore identified as giving in to "temptation" and the cooperating person is identified as the "sucker." In an iterated situation, however, these are not viable long-term strategy options, because eventually the person who is the "sucker" will either "die" (run out of resources) or adjust by also defecting.

Conclusion

Subsequent research has explored many variations in how the prisoner's dilemma can be structured, the strategies that actors can employ within those situations, and the interactions between the prisoner's dilemma structure and player strategy (e.g., Axelrod and Hamilton 1981). Cooperative behavior (mutual cooperation) clearly can occur between people, and it can be a behavior that is rational within certain environmental contexts, but it is also not guaranteed to be stable or rationally proscribed as those contexts change. The effects of these subtle variations on individuals' behaviors are some of the most fascinating and fruitful areas of research within this paradigm.

Prisoner's Dilemma, The

Simon Reeve
Oakland University, Rochester, MI, USA

Synonyms

Cooperation-defect; Logic game

Definition

A game in *Game Theory* involving a simultaneous choice between two players to either cooperate or defect, yielding four possible outcomes for each player based on the combination of choices between the players.

Introduction

The Prisoner's Dilemma game involves a simultaneous choice between two players – where each player makes a choice without knowing what the other player will do – to either cooperate or defect. In this game, defection yields a higher payoff than cooperation when paired with a cooperate choice from the other party, but if both defect they both do worse than if both had cooperated. In addition, the cost of being defected on, after providing a cooperate choice, is still greater. There is a total of four outcomes with the classic weighting of each being as follows: if both players cooperate they are awarded 3 points each, if they both defect they are awarded 1 point each, and if the first player chooses to cooperate and the other to defect then the one who has cooperated receives 0 points and the one who has defected receives 5. Receiving 0 points after being defected on is sometimes called the “sucker's payoff.” This point system is mirrored when framing the game around negative consequences rather than positive. Indeed, the classic framing of the game (giving it its name), the outcome is centered around prison terms of different lengths depending on outcome. The cover story involves a scenario where the police have arrested two suspects and are interrogating them in separate rooms. They are each offered a deal where they can go free if they confess, thereby implicating the other; the other option being to keep silent running the risk that if the other confesses then they (the cooperator) will receive the harsher punishment of 10 (or sometimes 5) years in prison for holding out. If both confess, each essentially trying to testify against the other, the deal is null and merely results in a standard sentence of 3 years each. If both remain silent however, the police only have evidence enough to charge them on minor offences

resulting in a 1 year prison term for each (see Axelrod 1984; Axelrod and Hamilton 1981). The basic structure of the game can be applied to a variety of scenarios such as arms races in international relations or business rivalries.

The Prisoner's Dilemma Game

At the core of the game as a one-time scenario is the logical solution that regardless of what the other suspect does, each can improve their own position by confessing. If the other remains silent, then the first can gain the most favorable outcome by confessing, taking the deal to walk free. If the other suspect confesses, then the first is still better off doing the same to avoid the largest sentence for a lone holdout. However, in a scenario of multiple rounds of the game, Robert Axelrod and William Hamilton (Axelrod 1984; Axelrod and Hamilton 1981) showed that an initial disposition toward cooperation paired with retaliatory defection if defected on the round before yields the most adaptive strategy. This strategy is dubbed the “tit-for-tat” strategy and shows how systems of cooperation may have evolved and are maintained (see entry on “The Evolution of Cooperation”). Essentially, one round of defecting on a cooperator yields an immediate 5-point payoff (or 0 year prison term). However, if this leads the other player defecting in the next round in retaliation, this will drop the initial defector's payoff to 1 point if they defect or 0 points if they shift to cooperation. Regardless, this leads to a lower or equivalent net payoff to mutual cooperation in both rounds (6 points total from 3 points per round). Continuing to defect and being defected on in return yields a much lower score than mutual cooperation across additional trials. Therefore, a tendency for cooperation – enforced when necessary by retaliatory defection – is the best strategy long term.

Conclusion

Within Game Theory, the Prisoner's Dilemma game involves a simultaneous choice between

two players to either cooperate or defect, yielding four possible outcomes for each player based on the combination of choices between the players. That is, each player makes a choice without knowing what the other will do – to either cooperate or defect – and each player’s outcome is dependent on the choice of the other player. The logical solution in a one-time scenario is that, regardless of what the other player does, each can improve their own position by defecting. However, in a scenario of multiple rounds of the game, an initial disposition toward cooperation paired with retaliatory defection if defected on the round before yields the most adaptive strategy.

Evolution of altruistic cooperation; Evolutionary altruism; Psychological altruism

Definition

We define two “problems of altruism.” The first is the classic problem of altruism, defined as the issue of how a behavior which decreases an individual’s lifetime reproductive success, while helping another individual (or individuals) increase their lifetime reproductive success, can evolve. We also define a “second-order problem of altruism,” where different authors have different conceptions of what does, and does not, constitute “altruism,” including approaches based on kin selection, multilevel selection theory, short-term altruism, and psychological altruism.

Introduction

Why would an organism help others at a cost to themselves, without any future reward or payoff? This, in essence, is the problem of altruism. Despite notions of “survival of the fittest” and “nature, red in tooth and claw,” seemingly altruistic acts abound in the natural world: meerkat sentinels famously forego feeding opportunities to guard the troop from predators; many species of mammals, birds, and fish engage in “cooperative breeding,” where subordinates sacrifice their own reproduction to help others breed; and humans regularly help others with no apparent benefit to themselves (e.g., giving blood, donating to charity, engaging in warfare). This altruistic behavior reaches its zenith in eusocial insects,

where huge swathes of the colony surrender reproduction altogether to help raise the offspring of a single queen (or handful of queens). Individual somatic cells within a body can also be thought of as altruistic, as only the germ line (sperm and eggs) is passed on to the next generation: all other somatic cells in the body therefore work altruistically in service of the germ line.

In all these cases, it would not appear to be in an individual’s interest to engage in such sacrificial behavior: for instance, a worker bee is not able to pass her genes down to future generations as they are unable to sire offspring of their own. Natural selection is generally believed to maximize individual fitness, yet the existence – and almost ubiquity – of altruism in nature clearly flouts this general rule and requires special explanation. Darwin appeared acutely aware of this issue, particularly regarding eusocial insects, and in *On the Origin of Species* Darwin (1859) wrote:

I...will confine myself to one special difficulty, which at first appeared to me insuperable, and actually fatal to my whole theory. I allude to the neuters or sterile females in insect communities: for these neuters often differ widely in instinct and in structure from both the males and fertile females, and yet, from being sterile, they cannot propagate their kind.

Over the next 100 years, a solution to this conundrum of how such altruistic behavior can evolve was touched upon by some (including Sewall Wright, Ronald Fisher, and JBS Haldane), but was not comprehensively addressed until William Hamilton in the early 1960s published his concept of “inclusive fitness” (Hamilton 1964). Rather than taking an organism’s individual fitness in terms of personal reproductive success, inclusive fitness partitions fitness into the effect of the focal individual’s actions on their own fitness (so-called *direct fitness*) and the effect of the focal individual’s actions on others’ fitness (so-called *indirect fitness*), which is weighted by the coefficient of relatedness (r) between the individuals. r is the probability that individuals share altruistic genes, above baseline levels of the gene(s) in the population. Ignoring rare cases like greenbeards, r is primarily due to genealogical relatedness (so r approximates 0.5 for full siblings, 0.25 for

aunts/uncles, and so on). This focus on genealogical relatedness has earned Hamilton’s theory the name “kin selection.”

Hamilton’s formulation presents a simple rule for when altruism can evolve. If c is the direct fitness cost to performing an action and b is the benefit to others (in terms of increased reproductive success), altruism can evolve when: $br > c$. This is known as Hamilton’s rule and demonstrates how altruistic behaviors – such as sterile worker castes in eusocial insects – can evolve. As a simple example, imagine that individuals only interact with full siblings. Individuals with the altruistic gene increase their partner’s reproduction by three children at a cost of a decrease in their own reproduction by one child. Given these parameters, $b = 3$, $r = 0.5$, and $c = 1$. Therefore, as $br > c$ ($3 * 0.5 = 1.5$, which is greater than 1), this behavior can evolve, even though it involves a cost to the focal individual’s direct fitness. This concept was pithily summarized by Haldane, who quipped that he would lay down his life for two brothers ($r = 0.5$) or eight cousins ($r = 0.125$).

Formal Definition of Altruism

From this Hamiltonian perspective, altruism is defined as a behavior which causes a decrease in an individual’s lifetime direct fitness but increases the lifetime fitness of others. The lifetime direct fitness consequences to self are therefore negative, while the lifetime fitness consequences to recipients are positive ($-/+$; where the first term is the direct fitness effect of the behavior on the focal individual (c) and the second term is the indirect fitness effect of the behavior on recipient’s fitness (b)). This is in contrast to mutually beneficial behavior which has positive lifetime fitness consequences for both parties ($+/+$). Together, altruistic and mutually beneficial behavior can be grouped together as “cooperation” (West et al. 2007). Behavior can also be selfish, which means it increases an individual’s direct fitness at a fitness cost to others ($+/-$), or it may be spiteful, in which case behavior decreases both the direct fitness of the focal individual and the fitness of the recipient ($-/-$; Table 1).

Problem of Altruism, Table 1 A classification of social behaviors based on their direct fitness effects on the focal individual (actor) and the fitness consequences for the recipient

		Fitness effect on recipient (b)	
		+ (positive)	– (negative)
Direct fitness effect on actor (c)	+ (Positive)	Mutual benefit	Selfishness
	– (Negative)	Altruism	Spite

Note that altruistic behavior does not necessarily require a decrease in personal fitness relative to selfish behavior if interactions are assortative, which occurs when altruists preferentially interact with each other (i.e., $r > 0$). Rather, altruism is defined as a decrease in *direct fitness*, rather than a simple decrease in *personal fitness* (which is an individual’s total reproductive success, so it includes help received from others; note that personal fitness is also known as “neighbor-modulated fitness”). When $r = 0$, altruists will always have lower personal fitness than selfish types, but when $r > 0$, altruists may have greater personal fitness than selfish types, given that altruists preferentially interact with and help one another. Regardless of whether a personal fitness or inclusive fitness approach is adopted, for any value of r , altruists will have lower direct fitness than selfish types. As this is all rather abstract, the difference between personal fitness and inclusive fitness is presented in Fig. 1, while a worked example comparing the two approaches in a simple prisoner’s dilemma scenario is presented in Fig. 2. The essential difference between the two is that inclusive fitness only considers an individual’s actions on their own fitness (direct fitness) plus the fitness benefit *given to* others (weighted by relatedness; indirect fitness), while personal fitness considers an individual’s actions on their own fitness (direct fitness) plus the fitness benefits *received from* others (indirect fitness). In the personal fitness formulation, r is conceptualized as the probability of correlated interactions between individuals with altruistic genes (rather than strict

genetic relatedness), although in most species the main reason for correlated interactions is genetic relatedness (Birch and Okasha 2015). Despite different conceptualizations regarding whether indirect fitness is classified as help given to others weighted by genetic relatedness (the inclusive fitness approach) or as help received from others and r as the probability of correlated interactions (the personal fitness approach), both approaches are (by and large) mathematically equivalent as they both predict that altruism can evolve when $br > c$ (Birch and Okasha 2015). For additional details of how to measure inclusive fitness, and various pitfalls to avoid, see Grafen (1984).

Altruism in the Real World

As recognized by Darwin, the behavior of non-reproductive eusocial insects seems to fit this definition of altruism, where individuals help their relatives reproduce, even though they engage in no direct reproduction. Cooperative breeding in vertebrates (such as meerkats, callitrichids, and several bird species) also follows a similar pattern as it often occurs between relatives, so non-reproductive individuals appear to gain indirect fitness benefits by helping their kin. Additionally, as predicted by Hamilton's rule, in insects, birds, and mammals, monogamy (and therefore high levels of sibling relatedness) precedes the evolution of cooperative breeding (Lukas and Clutton-Brock 2012).

Despite the empirical and theoretical attention received by indirect benefits as explanations for such seemingly altruistic behavior, in many cases other potential explanations based on direct fitness benefits may have been overlooked (Clutton-Brock 2002). For instance, cooperation among kin is not necessarily evidence of altruism if both parties increase their direct fitness, as can occur with reciprocity between relatives. As another example, seemingly altruistic sentinel behavior among meerkats may in fact be less costly than often assumed, as sentinels are not at an increased risk of predation (Clutton-Brock et al. 1999). Additionally, relatedness to the group does not predict sentinel activity, suggesting that indirect benefits to kin may not

explain this behavior. Rather, the best-fed meerkats are more likely to take up guard duty if a sentinel is not present already, suggesting that this behavior may be largely for selfish reasons to avoid predation.

Furthermore, cooperative breeding in birds – where subordinates help dominants raise the brood – is again often claimed to be due to indirect fitness benefits, as the helpers are often siblings of the chicks. Although these indirect fitness benefits are likely to be important, subordinates may also gain direct fitness benefits by increasing the survival of both themselves and the nest, then subsequently inheriting the breeding rights of the nest after their parents. This appears to explain variation in helping behavior among birds, where the sex which is more likely to inherit the nest provides greater levels of help, despite equivalent levels of relatedness (Downing et al. 2018).

In long-lived animals where all individuals can reproduce, it can be especially difficult to determine whether an organism is acting altruistically, cooperating for mutual benefit, or behaving for purely selfish reasons. Nonreproductive eusocial insects are a rather simplified example as all fitness has to be indirect since reproduction is impossible, but it is much harder to determine whether behavior is altruistic in humans and other animals, as most adults are capable of reproduction and lifetime fitness consequences are hard to measure. Thus, although altruism is easy to define, it may be hard to spot in practice (Grafen 1984).

Alternative Definitions of Altruism

The discussion above can be thought of as the “first-order problem of altruism,” which explains the difficulties in altruistic behavior evolving. Next, we discuss the “second-order problem of altruism” (or “the problem of the problem of altruism”), in which different authors use different definitions of “altruism.” This is especially common in the human literature, which is often by necessity cross-disciplinary, meaning that terms common to various disciplines may have different meanings within each discipline. We discuss three common second-order problems of altruism

which are frequently found in the literature. The first concerns different definitions of altruism from a multilevel selection approach, the second concerns altruism measured on different time scales, while the third concerns conflating evolutionary and proximate definitions of altruism. Although we have presented a definition of altruism derived from inclusive fitness above (which was used as it is the most common definition employed in evolutionary biology; West et al. 2007), we are not advocating that this is the only or correct usage. Rather, we are advocating that whichever decisions authors make regarding the term “altruism,” they are clear on which definition they are using.

Altruism and Multilevel Selection

While the definition above based on a kin selection framework is a common definition of altruism in evolutionary biology, it is not the only one that exists in the literature (West et al. 2007). Proponents of a “multilevel selection” (MLS) perspective on evolutionary change define altruism as a behavior which decreases individual fitness within groups but increases the fitness of the entire group (Sober and Wilson 1998). The long-term evolutionary trajectory is then determined by the relative strengths of within-group selection (which acts against altruism, as selfish types have greater fitness than altruists within groups) and between-group selection (which favors the spread of altruism, as groups with more altruists have greater fitness than groups with fewer altruists). Note also that although kin selection and MLS approaches appear rather different, they are equivalent approaches mathematically (Birch and Okasha 2015); they just partition fitness in different ways (kin selection into direct and indirect fitness effects; MLS into within- and between-group components). One view is therefore not necessarily more correct than the other: the difference between these frameworks is in perspective, not process. While kin selection approaches define altruism in absolute terms over the entire population, from an MLS perspective altruism is defined relative to the group. As will be discussed below,

this can lead to different expectations of when altruism can evolve, depending on whether one adopts an inclusive/personal fitness or MLS perspective.

Within the MLS framework, there are two flavors of altruism: weak and strong (Wilson 1990). Weak altruism occurs when altruists have lower fitness than selfish types within groups, but have greater fitness than if they were not altruistic. An example is riding a tandem bike: if one person pedals and the other does not, then the lazy rider exerts less energy than the individual who pedals (i.e., selfish types have greater fitness within groups), but the altruist has greater fitness than if they did not pedal at all, as at least if one person pedals they will reach their destination (Kerr and Godfrey-Smith 2002). This scenario is presented abstractly in Fig. 3a. As the altruist increases their own fitness by cooperating, this behavior is not altruistic from a kin selection perspective but rather may be mutually beneficial to both parties, or simply self-interested, as the benefit derived by others is an incidental by-product. As such, weak altruism does not require assortment, so this behavior can evolve in randomly formed groups (i.e., if $r = 0$).

In contrast, strong altruism occurs when altruists possess both lower fitness than selfish types within groups and lower fitness than if they were not altruistic. The example presented in Fig. 2 of a classic prisoner’s dilemma is an example of strong altruism (see also Fig. 3b). If group formation is random, then altruists have lower fitness compared to if they did not cooperate. Thus, if a behavior is strongly altruistic from an MLS perspective, then it is also altruistic from a kin selection perspective and thus requires assortment to evolve (i.e., $r > 0$).

One must therefore be careful when converting between altruism as defined from an MLS perspective (which often uses the multilevel price equation, which partitions selection into between- and within-group components; Sober and Wilson 1998) and altruism as defined from a kin selection perspective (which uses Hamilton’s rule of $br > c$). Under conditions of weak altruism, behavior may be altruistic from an MLS perspective, but not altruistic from a kin selection approach, as acting “altruistically” increases an individual’s direct

Problem of Altruism, Fig. 3 Strong and weak altruism, as defined from a multilevel selection perspective. The population consists of altruists (smiley faces with a halo) and selfish types (smiley faces with devil horns). (A) “Weak” multilevel altruism: altruists have lower fitness than selfish types within groups (i.e., in a mixed group, selfish individuals have greater fitness than altruists). However, given the choice between being an altruist and being selfish, individuals have greater fitness if they decide to be an altruist (as the fitness of an altruist in a group of one altruist and one selfish type is greater than the fitness of a

selfish type in a group of no altruists). (B) “Strong” multilevel altruism: as with weak multilevel altruism, altruists have lower fitness than defectors within groups. However, given the choice between being an altruist and being selfish, individuals have greater fitness if they decide to be selfish (as the fitness of an altruist in a group of one altruist and one selfish type is lower than the fitness of a selfish type in a group of no altruists). Weak altruism does not require assortative group formation in order to occur, while strong altruism does

fitness. Of course, which definition people use is subjective – and a plurality of approaches can help to understand problems in greater detail (Kerr and Godfrey-Smith 2002). However, it can cause confusion if different definitions of “altruism” are used synonymously (West et al. 2007).

Short-Term Altruism

Some authors define altruism in terms of short-term costs, rather than in terms of lifetime direct fitness (e.g., Fehr and Fischbacher 2003). For instance, in reciprocal altruism, individuals pay a short-term cost to cooperating, but it is not necessarily altruistic in the Hamiltonian sense defined above, as they increase their direct fitness in repeated cooperative interactions. That is, the behavior is mutually beneficial (+/+), rather than altruistic (-/+; although note that reciprocity is weakly altruistic from an MLS perspective, as groups of reciprocators outcompete selfish groups, even though in mixed groups selfish types have greater fitness than reciprocators; Sober and Wilson 1998). Several models of

“altruistic punishment” or “strong reciprocity” also appear to share this feature, where altruism is defined in terms of short-term payoffs, rather than in terms of lifetime direct fitness (e.g., Gintis 2000). These features, combined with a focus on between-group competition to spread such “altruistic” behavior, can make it difficult to determine whether the behavior in these models is altruistic from a kin selection perspective or not (Lehmann and Keller, 2006).

Evolutionary and Psychological Altruism

Up until now, we have been dealing with why altruism might have evolved and how it may be adaptive in a social environment. However, as with everything else in biology, the study of a behavioral trait concerns two distinct questions – *why* a behavior evolved and *how* the behavior works, i.e., the ultimate and proximate explanations. It is crucial to maintain a separation between these explanations when attempting to understand and explain any trait. For instance, knowing that individuals feel rewarded when they punish

defectors is a proximate answer for why humans punish, but it does not answer why the behavior evolved. An answer to this question would be an ultimate explanation in terms of individuals who detect and punish free riders having greater fitness than those who do not detect and punish free riders. In the case of altruism, evolutionary explanations deal with fitness considerations of individuals and groups, while psychological explanations are largely based on the *motives* of the actor.

We now look at altruism from a psychological perspective. Hamilton's theory postulated that altruistic behavior can evolve due to the inclusive fitness benefits it bears for the actor via indirect reproduction in kin. For these benefits to play a mechanistic role in behavior, however, they need to be experienced by the actor in the form of feelings, motivational factors, or moral factors (Monroe 1994). Psychological altruism deals with the understanding of such motivations that can drive one to benefit others at a cost to self (although unless directed toward kin, such psychologically altruistic behavior is generally framed as being short-term altruistic, rather than evolutionarily altruistic). Empathy, for example, is an emotional mechanism that can propagate other-regarding behavior, by creating a feeling of connectedness (De Waal 2008). By the psychological mechanisms of emotion contagion and perspective-taking, individuals can "put themselves in other's shoes" and act in the interests of others and against narrow short-term self-interest. Morality forms a cultural norm, as well as part of one's conscience, that can promote such seemingly altruistic behavior by dictating that one must help others, sometimes even at a cost to themselves. To the extent that these norms become internalized, other-regarding preferences – and therefore psychological altruism – can emerge.

Though ultimate evolutionary explanations do not consider the internal motives of an actor to determine altruism – after all, eusocial insects are evolutionarily altruistic, yet it would be unlikely to ascribe to them altruistic motives – the literature largely persists in using terms that are reflective of these motives. Actions are called "selfish" or

"altruistic" based on whether the actor only seeks benefits for herself or intends to benefit another. This oftentimes ensues confusion between evolutionary and psychological altruism and leads to conflation of terms. Since these terms also have high vernacular use – which are mostly to do with one's motives – they can cause further confusion in the evolutionary understanding of altruism (Sober and Wilson 1998). Some authors use evidence of psychological altruism to claim that some human behavior is evolutionarily altruistic. For instance, Richerson and Boyd (2005, pages 216–221) review evidence for empathy and seemingly altruistic cooperation in one-shot economic games with strangers (to be discussed below) and conclude that humans possess other-regarding preferences. They then use this evidence for psychological altruism to argue that evolutionary altruism toward nonkin may also exist. However, as a general rule, there is no clear relationship between evolutionary and psychological definitions of altruism, and they should not be confused with one another or used interchangeably. Behaviors that are psychologically altruistic can be evolutionarily either selfish or altruistic and vice versa.

An example to demonstrate this is a man saving a drowning (unrelated) child. This behavior may decrease the man's lifetime direct fitness (and increase the fitness of the child) and therefore be evolutionarily altruistic. Alternatively, although this behavior involves a short-term cost, this behavior may increase his direct fitness if he is more likely to be chosen as a future reciprocal trading partner or as a mate, in which case this behavior is not evolutionarily altruistic. Similarly, the man's intentions may be psychologically altruistic if he genuinely cares about the child's welfare. However, his motives may not be altruistic if he perceives the scenario as a chance to enhance his reputation, rather than caring about the child. Thus, to classify an act as psychologically altruistic, the actor must *intend* to bring benefits to the recipients, even at a cost to themselves. But definitions of altruism based on intentions are separate from definitions of altruism based on whether behavior is detrimental to evolutionary fitness.

Does Psychological Altruism Exist?

While determining an actor's true intentions and motivations is a difficult task, many psychologists and economists often take a rather pessimistic view toward psychological altruism, in which altruistic acts are treated as a subtle variant of self-interest. For instance, altruistic acts have been explained from an egoistic perspective, in which actors help others solely in order to reap future benefits, for instance, by forming reciprocal relationships. Alternatively, these acts have been explained from an egocentric perspective, in which actors behave altruistically if watching the pleasure of her beneficiaries exceeds the satisfaction of consuming the commodity itself (Khalil 2004). According to both these views, no act is truly psychologically altruistic since the actor gets either reputational advantages or feels pleasure and internal gratification from their seemingly altruistic acts (altruistic hedonism). This pessimism has been well captured by Ghiselin (1974) in the following lines, "What passes for cooperation turns out to be a mixture of opportunism and exploitation... Scratch an altruist, and watch a hypocrite bleed." Based on these motivations, economists sometimes partition altruism into pure and impure altruism; in pure altruism, the only motive of the actor is the outcome of the altruistic act itself (e.g., aid being given to children in need), whereas in impure altruism, the impact on the recipient's welfare is not the primary motivator, as instead the actor gets a "warm glow" or feeling of goodness, which comprises a private benefit (Andreoni 1990).

However, despite these difficulties of determining whether an act is psychologically altruistic or not, some experiments have indicated that certain aspects of human behavior are indeed motivated by a concern for others' welfare. This optimistic view was endorsed by Adam Smith (1759) who wrote that,

How selfish soever man may be supposed, there are some principles in his nature, which interest him in the fortunes of others, and render their happiness necessary to him, though he derives nothing from it except the pleasure of seeing it.

The empathy-altruism hypothesis (Batson et al. 1987) claims that empathy evokes motivation to reduce the other's need, promoting altruism, and that self-benefits from such acts are simply unintended consequences of the ultimate goal (helping the other). In a series of experiments conducted by Piliavin et al. (1981), there were various degrees of emotional responses in reaction to seeing someone in need. Piliavin and colleagues quantitatively described a low magnitude emotional response to other's needs in non-emergency situations as empathy, such as feeling sympathetic, compassionate, or tender, and a high magnitude emotional response to other's needs in emergency situations as personal distress, such as feeling alarmed, upset, or disturbed. These emotional and psychological responses to other's needs are hypothesized to provide the motivation for other-regarding behavior in humans (Batson et al. 1987). These and other experiments suggest that humans, at least in part, are motivated by a concern for the welfare of others, indicating that psychological altruism may indeed exist.

Case Study of Human Altruism: Behavior in Economic Games

Numerous experiments have demonstrated that humans behave seemingly altruistically in experimental economic games, where the optimal strategy is to free ride on the cooperation of others: in all societies tested, humans frequently cooperate with strangers, contribute to public pools, punish selfish individuals at a personal cost in one-shot interactions, and even punish those who defect on others (so-called third-party punishment; Henrich et al. 2005; Bernhard et al. 2006). This behavior appears both evolutionarily altruistic – as individuals help others at a cost to self, despite a lack of repeated interactions or reputational effects – and psychologically altruistic, as individuals appear motivated to assist others and enhance their welfare.

However, leaving aside the question of whether behavior in these games is psychologically altruistic, the assumption that such behavior is detrimental to fitness, and therefore evolutionarily altruistic, has been questioned on several

fronts. First, although this behavior is seemingly altruistic in the context of the game (and is certainly short-term altruistic), the strategies adopted by players in these games may be mutually beneficial when applied outside the lab in real-world settings. The costs of mistaking repeated interactions for a one-shot interaction may be high, in which case seemingly irrational cooperation in one-shot encounters may evolve (Delton et al. 2011). Second, the design of these experimental games is likely to be unfamiliar to most participants, which means that individuals tend to use behavioral strategies from outside the lab (which are likely to be more cooperative than the optimal behavior in these games) when first playing these games. Supporting this interpretation are findings that individuals with greater experience in these games are less cooperative than “naive” participants, presumably because they have learned that it pays not to cooperate in these situations (Rand et al. 2014). Third, it is very difficult to know exactly what behavior in these games means in terms of real-world cooperation, as the external validity of behavior in these games is often low (Gurven and Winking 2008); although substantial levels of cooperation toward strangers are observed in these experiments, in the real-world unsolicited cooperation toward strangers is much rarer (Winking and Mizer 2013). Of course, perhaps behaviors in these games (and some behavior in the real world) are examples of evolutionary altruism, but it is very difficult to know definitively, and these alternative interpretations cast doubt on the conclusion that some cooperative behavior in humans (at least toward nonkin) is altruistic.

Conclusion

The concept of altruism has a fraught intellectual history, with numerous varying and conflicting definitions in use. With the term “altruism” being used across disciplines, like evolutionary biology, economics, psychology, and philosophy, it is impossible to classify altruism by a single agreed-upon definition. This plurality of approaches

means that authors – especially those engaging in cross-disciplinary work – need to clearly define what they mean by “altruism,” in order to forestall misunderstandings and unnecessary confusion. This is especially pertinent for the distinction between evolutionary and psychological altruism. In this chapter we have attempted to describe various definitions of altruism found in the literature, including Hamiltonian altruism, multilevel selection altruism (both weak and strong), short-term altruism, and psychological altruism, as well as the links – or lack thereof, in the case of evolutionary and psychological altruism – between these definitions. Given this multitude of definitions, it is no wonder that, despite being a topic of interest for centuries, we still do not have an established understanding and consensus on “what is altruism” and whether much human behavior is in fact altruistic (both from evolutionary and psychological perspectives). Clarifying one’s own meaning of altruism can go a long way to solve this second-order problem of altruism and allow coherent interaction between disciplines in order to understand whether, and under what circumstances, altruism may evolve.

Problem of Cheating

Jacob Dye and Ethan Solomon
School of Psychology, University of Newcastle,
Callaghan, NSW, Australia

Synonyms

Cheat; Defector; Free-rider; Manipulation

Definition

Cheating is a strategy or behavior that exploits social agreements of cooperation; from a genetic fitness perspective, cheating benefits the cheat while causing detriment to the cooperator.

Introduction

Cheats or free-riders are organisms that take advantage of the cooperative social behaviors of other organisms either within or outside of their species in order to obtain resources and/or mating opportunities while incurring less cost than would normally be associated with their acquisition. Ghoul et al. (2014, p. 319) define cheating as “(i) a trait that is beneficial to a cheat and costly to a cooperator in terms of inclusive fitness (ii) when these benefits and costs arise from the actor directing a cooperative behavior toward the cheat, rather than the intended recipient.” However, the term “cheat” has been used somewhat inconsistently throughout the evolutionary and ecological literature leading some researchers to suggest that the term is possibly inappropriate when applied to organisms other than humans. These researchers argue that the term “cheat” anthropomorphizes and implies a level of conscious intent that appears to be absent in many cases (Douglas 2008). Further, cheating has been defined in a multitude of ways (e.g., see Ghoul, Griffin, and West’s appendix). However, Ghoul et al. (2014) have since attempted to clarify the term by disambiguating the kind of cheating

occurring based on disentangling four important distinctions. Firstly, whether cooperation between the organisms is possible, if cooperation is not possible, then there would be no selection pressure for cheating; secondly, whether the behavior of the “cheat” involves deception, if deception is involved, then the cheat is exploiting a signaling system; thirdly, if the organisms are of the same or different species; and, finally, if the behavior is obligate or facultative. Facultative cheats use a strategy that is conditional on the behavior of their social partner, whereas obligate cheats use a fixed strategy such as always gathering less resources than the cooperators. Because cheating requires social cooperation, to discuss the problem of cheating, it is first important to discuss the prosocial or society promoting/maintaining cooperative behaviors that are performed by social organisms and exploited by cheaters. Secondly, we will discuss cheaters and the detection of cheaters by their social group. Finally, we will consider the idea that cheating and the detection of cheating are psychological mechanisms that evolved as part of an evolutionary arms race. For the purposes of this entry, we will discuss cheating as it applies to human cooperative groups. However, it is important to note that cheats have been reported in a diverse range of organisms including parasites, insects, fishes, reptiles, amphibians, birds, and mammals (see Ghoul et al. 2014, p. 319 for table of applicable sources).

Theory and Evidence

Initial research ideas surrounding behaviors that help another at a cost to the actor were discussed by social psychologists as being acts of “true” altruism, the idea of giving and receiving no benefit in return. However, like many theories of social behaviors with inherent biological consequences, the standard social science model fell short (for a good review of the ongoing argument between evolutionary theory and the standard social science model, see Burke 2014). The problem is that altruistic behaviors result in fitness benefits for both the actor and the receiver. Hamilton (1964) first posed the idea that altruism

passed between kin actually benefited the actor by way of inclusive fitness. That is, by helping family members, the actor is actually increasing the likelihood that some portion of their unique genetic makeup will persist in the species. Self-sacrificing behaviors between kin occur when the cost to the actor is lower than the benefit to the receiver. Hamilton's rule can be reduced to $c < rb$ where c is the cost, r the coefficient of relatedness, and b the benefit. Benefit passed to offspring is considered direct fitness, while benefit passed to other kin is indirect fitness. Direct and indirect fitness in combination equals inclusive fitness. Trivers (1971) extended on these ideas by introducing the theory of reciprocal altruism showing how behaviors associated with inclusive fitness when they occur between kin could have similar results when practiced reciprocally within social groups. Fitness benefits for the actor and receiver through reciprocal altruism (or reciprocity) in social groups only requires that the benefit to the receiver is greater than the cost to the actor, that the organisms are capable of recognizing individual members of the group, and that the organisms have a reasonably long life span. Trivers (1985) later stated that modern human societies fulfill the three prerequisites for reciprocity to occur, aid-giving between friends that is later reciprocated has been noted cross-culturally, and we have developed an emotional system that encourages cooperation. Because cooperation within the human species has resulted in the formation of societies, it has ultimately increased the fitness of those included within those societies. It is for this reason that we have evolved an emotion system that encourages cooperation, with positive emotions such as happiness and pride rewarding caring, cooperation, and reciprocation whereas punitive negative emotional experiences such as guilt and shame discouraging cheating, manipulation, and violence (Nesse 1990). The link between reciprocation and positive emotional and societal rewards can be seen in pre-industrialized societies such as the !Kung San of the Kalahari in Africa. The !Kung San have strong social traditions built around sharing the spoils of a successful hunt; failure to do so results in loss of social status. Sharing does not occur as an act of pure altruism;

reciprocation is expected when the fortunes are reversed. In this way reciprocal giving serves to increase inclusive fitness of all members of the !Kung (Harris 1998).

From a genetic point of view, Dawkins (1976) gave a strong argument for why "true" altruism could not exist. In *The Selfish Gene*, Dawkins outlines the argument that biological organisms are simply the vehicles of evolution, which for a brief period in time carry the replicators (genes). The replicator that most effectively promotes copies of itself (the selfish gene) will persist for an indeterminately large number of generations, whereas the replicator that promotes copies of other genes will fail to replicate as much and be removed from the gene pool more quickly. In other words, the genes for "true" altruism would not have persisted in the gene pool. The divide between "altruism" and reciprocity continues to be a contentious topic between researchers who follow the standard social science model and evolutionary theorists. Daly and Wilson (1983) give an illuminating explanation as to the source of this contention stating that altruism can exist as a proximate cause of behavior; organisms can display self-sacrificing behavior in order to benefit another. But using ultimate causation, if this altruism increases the fitness or inclusive fitness of the actor over a generational time scale, then it is ultimately a selfish behavior. So while making a large donation to charity may seem like an act of great altruism when viewed proximally, when viewed ultimately over the expanse of generations, the reputational benefits of making this donation will increase the actor and/or their kin's fitness.

Other forms of aid-giving between organisms have been identified. Clutton-Brock (2009) suggests that mutualism and manipulation are two ways in which aid can be given by conspecifics without reciprocation. Mutualism involves both parties benefiting at the time of the behavior, i.e., hunting in groups for shared food. Manipulation involves the use of coercion in order to receive aid with no intention of reciprocating. Both involve no cost-benefit asymmetry which must be repaid at a later time, differentiating them from reciprocation. However, both reciprocation and

mutualism involve a form of social contract or understanding of cooperation. Mutualism involves immediate cooperation, where the efforts of both individuals in combination allow them to obtain the resource successfully, whereas reciprocation involves the understanding that the giving of aid at one time will result in the receiving of aid at another. Both of these social strategies improve the fitness of the organisms and potentially their kin. However, both strategies are also vulnerable to exploitation through cheating. Due to this vulnerability, human cooperation is based on three evolved prepositions; firstly to seek cooperation that is of net benefit to both parties (whether in the long or short term), secondly to share cooperatively acquired resources with the group, and thirdly to punish free-riders and cheats. Because of the fitness benefits associated with successful cooperation, there would be evolutionary pressure to adapt ways of identifying and neutralizing cheats (Tooby et al. 2006).

Free-riders or cheats reap the benefits of cooperation without paying the costs, and this behavior places them at a competitive advantage (at least in the short term) (Tooby et al. 2006). Cheating also reduces the fitness of the victim as they either do not receive or receive less reciprocation or mutual benefit than the social rules would suggest. Social rules exist in order to maintain stability within the group. Cheating involves the violation of deontic social rules and is only considered nefarious (and subsequently detected) when three criteria are met. The cheater benefits, acted intentionally, and cheating was possible (Cosmides et al. 2010). Social predator phenotypes have been identified within the human species. Psychopathic individuals victimize others and are characterized by a callous disregard for others, lack of empathy, deception, lack of guilt, and impulsivity (Book et al. 2007). Although these characteristics appear to be detrimental as a long-term social strategy, they also result in short-term resource and mating opportunity benefits through the use of a cheater strategy. For example, impulsivity and a lack of empathy allow one to exploit the trust of another to obtain resources within a short window of opportunity, without guilt or thoughts of consequences hindering the act. This has been observed by Gervais et al. (2013) who found that

individuals high in psychopathic traits defect in prisoner's dilemma games when they perceive their relation to the other player as being of low value. Therefore, when opportunities arise to obtain resources from others that carry a low risk of consequences, individuals high in psychopathic traits are extremely likely to take advantage. Although socially predatory behavior within human societies often carries consequences, the immediate benefits of this predatory behavior suggest that psychopathy is an evolved adaptation related to use of a cheater strategy (among other things) and useful in resource-poor environments (Mealey 1995). An interesting question is if humans receive fitness benefits from social cooperation, how does a phenotype like psychopathy that is seemingly designed to optimize cheating behaviors evolve? Further, if cheating confers fitness benefits and discourages cooperation, how do genes that promote cooperative behaviors persist in the gene pool?

The evolutionary arms race theory may explain the evolution of both cheaters and mechanisms that promote cooperation and the detection of cheaters. According to this theory, a reciprocal relationship exists between predator and prey both within and between species. This relationship is referred to as an evolutionary arms race or coevolution and is the driving force of many evolutionary adaptations across both predators and their prey (Dawkins and Krebs 1979). An elementary example of an evolutionary arms race is the adaptation of speed shared between foxes and rabbits. Slow rabbits in a population are easily eaten by foxes, and thus natural selection favors faster rabbits. Consequently, there are fewer slow rabbits in the environment for slow foxes to eat, and therefore natural selection also favors the faster foxes. In this way, the slow rabbits effectively fuel an arms race that forces both species to adapt over generations and become progressively faster than their predecessors (Dawkins and Krebs 1979). Applying the same concept to humans, we can see that cooperation between individuals in society improves each individual's genetic fitness. However, cooperation is subject to cheating, and in comparison with cooperation, cheating results in increased benefits at a reduced cost. Because of this there

would be evolutionary pressure to cheat as well as evolutionary pressure to adapt ways of correctly identifying cheaters (Tooby et al. 2006). Those cooperators who are more successful at identification and avoidance of cheating would have increased likelihood of passing on their genes. However, when cooperators become aware that cheating is occurring, their natural response is a desire to punish the cheaters in order to either stop their cheating behavior or remove them from the group (Price et al. 2002). Being punished reduces the genetic fitness of the cheater as they then have reduced access to resources and mating opportunities. So individuals in society adapting to the presence of cheating by developing mechanisms of detection increases evolutionary pressure on cheaters to cheat more effectively, so that cheaters who remain undetected have a higher likelihood of passing on their genes. More effective cheating increases evolutionary pressure on cooperators to further enhance their cheater detection capabilities, and so the arms race continues.

Research on cheater detection has revealed much about our ability to identify and cope with those who seek to exploit us but little about the differences between those who successfully identify and avoid cheaters in comparison with those who become victims. For example, the vast majority of studies with the prisoner's dilemma game have focused on the dark triad personality traits – psychopathy, narcissism, and Machiavellianism – and how these factors influence the cooperativeness (or lack thereof) of players in the game (Gervais et al. 2013). Becoming a victim of cheating or exploitation is potentially a consequence of a reduced ability to detect cheaters or a lack of an ability to successfully alter behavior in order to avoid cheaters upon having detected them. The focus of research appears to be around understanding those who seek to cheat and fail to identify the evolutionary function of the victims themselves. This may be partly due to a societal taboo around the suggestion that individual differences may contribute to an increased likelihood of being victimized. This taboo takes the form of accusations of “victim-blaming.” However, understanding the individual differences between those who are victimized and those who successfully identify and avoid cheats is ultimately an area

of research seeking to enhance cooperative behaviors within society.

The general population has developed adaptive mechanisms like cheater detection to be sensitive to cues of predatory behavior (such as lying or not honoring agreements) in order to successfully navigate encounters with potential cheats without losing resources. If such an arms race does exist between cheaters and cooperators, individuals who are victimized may serve an evolutionary purpose – by losing one's resources to predatory behavior, the general population receives short-term benefit by way of an increased likelihood of discovering the presence of the predator and the predator's methods. The cooperators also receive long-term adaptive benefits in that those individuals who have not adapted effective cheater detection mechanisms have lower levels of inclusive fitness, and as a result, their genes will eventually be removed from the gene pool (Verplaetse et al. 2007).

A neural module has previously been suggested as the mechanism for detection of cheaters, fittingly called the cheater detection module (CDM). It has been theorized that the CDM indicates the presence of unequal exchange in the context of reasoning about social contracts (a social agreement where a cost is incurred and a benefit is received). Evidence for the CDM has been observed through an adapted version of the Wason selection task (Cosmides 1989).

The Wason selection task (Wason 1968) requires the use of logic to test a deontic rule (a conditional rule, i.e., if A occurs, B must also occur) in the most efficient way. For example, if the conditional rule is “if a card has the letter A on it, it must have an even number on the other side,” and there are four cards, marked “A,” “B,” “2,” and “3,” the most efficient way to test the rule would be to turn over the card marked “A” (to test if there is an even number on the other side) and the card marked “3” (to test if the letter A is not on the other side). Griggs and Cox (1982) found that when the Wason selection task was altered to place, the participant as a police officer looking for underage drinker participants did significantly better than normal. Manktelow and Evans (1979) suggested that increased success on the amended task was because the task was less abstract but

found that participants did not do as well when other concrete tasks that did not focus on the enforcement of social rules were developed. Simply removing the context of being a police officer enforcing a rule significantly decreased performance. Cosmides (1989) argued that the increase in performance is due to an adaptive cognitive module designed to identify cheating behaviors.

As a result Cosmides (1989) produced an adapted version of the Wason selection task (Wason 1968) that follows the same logic as the original task; however the deontic rule is framed in the context of a social exchange (e.g., if the car is borrowed, it must be returned with a full tank of fuel). While performance on the original Wason task is notably poor (average of approximately 30% correct), Cosmides (1989) discovered that when the task was framed in the context of breaking a social contract, performance increased dramatically (approximately 70% correct). Cosmides (1989) suggests that this is evidence of the existence of a neural module designed specifically to recognize when one has been cheated in a social exchange. As mentioned earlier social rules exist in order to maintain social stability. Cheating involves the violation of these rules and can be detected when the cheater benefits, acted intentionally, and cheating was possible. Cosmides et al. (2010) showed evidence for this in a series of experiments that manipulated the presence of a benefit, the possibility of cheating, and the cheaters intentions, finding that people were more accurate at identifying cheaters when all three conditions were met. Evidence for a cheater detection module has been replicated cross-culturally with Cosmides and Tooby (1992) replicating the effect using a sample of Ecuadorian foraging people. However, the existence of the CDM has been brought into question through criticism of Cosmides' interpretations and the integrity of the adapted Wason selection task itself (Buller 2005). Although this position has been refuted and potentially falsified (Cosmides et al. 2010), the topic remains controversial, and few alternative tasks have been designed to capture cheater detection. If there is a specifically evolved module, it makes sense that it would be activated in other experiments that utilize social contract violation situations.

One alternative task that has previously been used to capture cheater detection is the prisoner's dilemma game (Verplaetse et al. 2007). The original prisoner's dilemma places two theoretical co-conspirators in separate interrogation rooms where they must choose whether they will sell out their co-conspirator for a reduced sentence. Subsequently, the prisoner's dilemma has been developed into a game that can be played for money or points based on a payoff matrix (Verplaetse et al. 2007). In this game, players choose to either cooperate (share a reward with another player) or defect (take a reward for themselves). There are three possible outcomes in the game: (1) If both players choose to cooperate, they share a reward equally. (2) If one player chooses to cooperate and the other chooses to defect (cheat), the cooperator will not receive a reward, and the defector will receive a large reward (greater than if they had cooperated) for themselves. (3) If both players choose to defect (cheat), they will each receive the smallest possible reward. Much research has focused on the optimum strategy for this game, showing that the strategy that is most effective is dependent on whether it is a single game or an iteration of games. In an iterated prisoner's dilemma performance in the game relies upon the degree to which one player correctly determines the cooperative tendencies of the other player. Maynard Smith (1974) states that as long as most members of a group follow a tit-for-tat strategy (cooperate first and subsequently do what your partner did in the previous round), it is mutually beneficial for both parties. This strategy encourages future cooperation through an initial act of cooperation and allows for retaliation and forgiveness to defectors. Those who fail to follow this tit-for-tat strategy fall into two categories: cheaters and "suckers." If two people cheat, then they receive very little reward, so cheating is only a successful strategy when there are few other cheaters in the game. Further, if you fail to recognize the cheating behavior of your partner and cooperate with them, then you get no reward. In this way the iterative prisoner's dilemma game is seen as analogous to cooperation and cheating within human societies.

Interestingly, evidence shows that cooperators can identify cheaters by their facial expressions. Verplaetse et al. (2007) obtained photos of

participants' faces while playing the prisoners dilemma game for a real monetary reward. Photos were taken at the exact second the participant indicated their decision to cooperate or defect. These photos were shown to another participant pool, who were asked to discern if the person in each photo cooperated or defected. It was found that approximately 66% of defectors (or in other words cheaters) were successfully detected by participants based on facial cues alone. A memory bias was also present for defectors in a surprise memory test. This provides evidence that humans can utilize facial cues to successfully detect cheaters and may have specific mechanisms designed for remembering them. Perhaps those who fall victim to cheating do so partially because of an inability to detect facial expressions signaling that behavior.

However, if the cheater cannot be identified, then the cooperators may suspend cooperation (Price et al. 2002). The most impactful cost of the presence of cheaters is that it results in reduced or suspended cooperation within the group so that reciprocal behaviors that would have occurred previously cease to occur (Tooby et al. 2006). Fehr and Schmidt (1999) conducted a meta-analysis of studies using public good games. Public good games involve the depositing of some valuable into a shared pool, provided that all parties deposit something into the pool, a third party then increases the pool (usually $1.5\times$ the value of the pool) as a reward for cooperation. In this way all parties become richer on average. Fehr and Schmidt (1999) noted that parties are initially quite generous with their donations to the shared pool. However, after repeated iterations of the game, most parties contribute nothing. This is because they perceive others to be not contributing. Cheating in these public good games results in the suspension of cooperation. Another theory postulates that those who have experienced prior victimization may perform poorly in cheater detection tasks and cooperate less as they learn maladaptive strategies to avoid further victimization. Gollwitzer et al. (2012) discovered that individuals high in victim sensitivity (a personality trait that influences individuals' perceptions of unfairness) underestimate the trustworthiness of others and are less cooperative in ambiguous interactions as a result. As victim sensitivity is

predicted by prior experiences of actual victimization (Gollwitzer et al. 2015), it is possible that individuals who have previously experienced victimization may become wary of even well-intentioned individuals when making social judgments. This causes them to suspend cooperation and may contribute to poor performance in cheater detection tasks.

Conclusion

Cheating results in immediate consequences for the cooperator who failed to detect the cheating behavior until it was too late. These consequences, especially when incurred repeatedly, can result in decreased genetic fitness and ultimately a reduced chance of passing on your genes. However, the broader implications of cheating behavior are that it discourages cooperation and thus broadly affects the viability of the group. For the cheater this behavioral strategy can result in fitness benefits, provided that there are not a large number of other cheaters in the group and they remain undetected. The problem of intraspecies cheating in humans may have acted as the catalyst for an evolutionary arms race, serving to increase adaptations for both cheating and cheater detection.

Synonyms

Heritability; Missing heritability

Definition

Genetic inheritance refers to the transmission of genes from one generation to the next. In sexually reproducing species, offspring inherit 50% of their genes from each parent.

Introduction

Genetic inheritance is often defined in terms of heritability, which is the portion of phenotypic variance in a population that is attributed to “genetic differences” among individuals in that population (Plomin et al. 2013). We place genetic differences in quotes because genomic variation is only implied and not directly examined. Generally speaking, a trait is heritable to the extent that it is transmitted through biological mechanisms from one generation to the next. This includes genomic mechanisms of inheritance as well as other biological mechanisms such as passage of epigenetic marks and transmission of nutrients or bacteria from maternal circulation (Meaney 2010). In this article, the terms “genetic” and “heritable” are used to capture both genomic sequence variation and other biological mechanisms of familial transmission collectively.

There are two forms of heritability: (1) broad sense and (2) narrow sense. Broad sense heritability (H^2) includes all sources of biological inheritance that contribute to the familial transmission of a trait. These include additive genetic effects, gene-by-gene interactions (epistasis), gene-by-environment interactions (GxE), possible epigenetic inheritance, and several others (Barnes et al 2014; Meaney 2010). Narrow sense heritability (h^2) posits that only additive genetic effects contribute to trait heritability and therefore assume other sources of biological inheritance are zero, which is the standard twin model assumption (see Twin Models). This assumption may be problematic, however, the relative contributions of genes and environments inferred from these models may be systematically over- or underestimated when nonadditive genetic factors are left unaccounted (Barnes et al. 2014).

Narrow sense heritability is estimated by partitioning trait variance into additive genetic and environmental components via statistical modeling. This technique involves measuring neither genes nor environments and instead infers their relative contribution via latent variables. As such, heritability is a statistical characterization of genetic and environmental influences rather than a biological one. Because heritability describes the portion of differences between individuals in a given population that can be attributable to additive genetic effects, heritability cannot be applied to explain the phenotype of an individual. For example, height heritability in humans is approximately 80% (Yang et al. 2010), but it is not accurate to say that 80% of the reason a person grows to their given height is due to genetics and the rest is environment. Heritability is also population specific. That is, a given heritability estimate is specific to the population from which it was derived at the particular time and space it was measured. A heritability estimate derived from a given population can change over time within that population, and the heritability of a trait measured in one group does not necessarily translate to another group.

The problem of genetic inheritance in the life history context is an extension of broad and narrow sense heritability when viewed through the lens of alternative strategies and conditional adaptation (Rowe et al. 1997; Belsky 2000). When applied to human development, hypotheses derived from life history theorizing often take the form of conditional adaptations (or developmental plasticity more broadly), which can be conceptualized as gene-by-environment interactions (GxE; part of broad sense heritability). Alternative strategies resemble the sole influence of additive genetic effects (narrow sense heritability), which assume no environmental influences. The biological mechanism that entrains life history development via conditional adaptation in humans is not well known; however, research using animal models and some preliminary human research point to epigenetic modification as a key developmental life history strategy regulator (Ellis 2013). Gene-by-environment interactions, epigenetics, and other forms of

gene-environment interplay may help elucidate why research using measured genes have fallen short of explaining phenotypic variance of the magnitude typical of behavioral genetic models (i.e., missing heritability).

Alternative Strategies

Theory and research in evolutionary biology have converged on the conclusion that it is unlikely that a single “best” genetically underlain phenotype will evolve (at least for most species; see Boyce and Ellis 2005). Alternative strategies represent one way in which genetic diversity is maintained in a population. Alternative strategies refer to individual differences in phenotypic profiles that are strongly genetically regulated (i.e., alternative phenotypes are influenced by major genetic effects). The basic concept behind alternative strategies is that they are underlain by genetic polymorphisms, and different suites of genetic variation are strongly related to two or more phenotypes. Alternative strategies can evolve, for example, when the different phenotypes have equal fitness in the population as a result of the relative frequency of each alternative.

A classic example of frequency-dependent selection is the Hawk-Dove model, which describes in mathematical terms how two alternative antagonistic phenotypes can be maintained in a population (Maynard Smith 1982). Consider a circumscribed population where members have either a Hawk or a Dove phenotype. The Hawk phenotype is characterized by fighting and escalating aggression until injured or the opponent retreats. The Dove phenotype is characterized by aggressive display but will retreat if the fight escalates. If a Hawk encounters a Hawk they will fight until one is injured. If a Dove meets a Dove they display until one gets tired and quits. Importantly, neither phenotype alone can comprise a stable population. A population of all Doves could be infiltrated by a Hawk who would gain huge fitness benefits relative to Doves. Likewise, a population of all Hawks could be very costly for the Hawk members, and a Dove that enters this population could reap

disproportionate benefits by avoiding injury. Over evolutionary time, a stable ratio of Hawks and Doves could evolve based on the relative costs and benefits of each phenotype.

Alternative strategies may be evolutionary advantageous when the genetically regulated phenotype matches well to the developmental and/or adult reproductive environment. It would be evolutionarily advantageous for parents to produce some children with alternative strategies that are largely impervious to socialization from the parent or other sources and who would thrive in particular contexts that fit their proclivities (Belsky 1997). Alternative strategies may also be more advantageous in multination environments, where cues to future environments are unreliable (Ellis et al. 2006). However, highly penetrant genotypes are rare and, when applied to thinking about alternative strategies, should be considered probabilistic and encompassing a disposition range toward a phenotype that is malleable to environmental influences, although distinct from conditional adaptations. Most complex behavioral traits, such as life history strategies in humans, are multiply influenced by both genes and environments and both developmentally and concurrently.

Conditional Adaptation

It is important to keep in mind that evolutionary processes do not act on genes directly. Instead, selection pressures act on phenotypes that are genetically influenced. Alternative strategies are one way that phenotypic diversity is maintained in a population (predicated on corresponding genetic diversity). A second way is conditional adaptations. Conditional adaptations are: “evolved mechanisms that detect and respond to specific features of childhood environments, features that have proven reliable over evolutionary time in predicting the nature of the social and physical world into which children will mature, and entrain developmental pathways that reliably matched those features during a species’ natural selective history” (Boyce and Ellis 2005, p. 290). Due to environmental variation within the lifetime of an

organism, such as food availability and social and reproductive ecologies, selection should tend to favor phenotypic plasticity, where an organism can facultatively adapt their phenotype to better fit a changing and/or anticipated future environment. Individuals may be genetically identical in terms of neurobiological substrates but produce very different and environmentally contingent phenotypes (Rowe et al. 1997). Key to the idea of conditional adaptation is that contingent phenotypes are nonrandomly organized and are the result of selection pressures that favored one trajectory over another based on specific environmental information during development. Plasticity may not always be the best option, however, if the costs for maintaining plasticity mechanisms are high or if there are not reliable cues that can than entrain a developmental trajectory fit to a future environment. In such cases, alternative strategies would be favored by natural selection.

Gene-Environment Correlation

Gene-environment correlations are important to consider when evaluating conditional adaptation hypotheses since, in the absence of genetic controls, strictly environmental analyses cannot rule out this third variable confound (Ellis et al. 2012). Gene-environment correlations are another way heritability can obfuscate life history hypothesis that involves developmental plasticity. There are three types of gene-environment correlation: (1) passive, (2) active, and (3) evocative (Jaffee and Price 2007). Passive rGE occurs when the correlation between the gene and environment is the result of being born in that particular environment. For example, there is a correlation between father absence (the environment) and pubertal timing in girls. Multiple theories and mechanisms have been offered to explain this association (Ellis 2004), including passive rGE. In this case, the association between father absence and pubertal timing is hypothesized to result from daughters inheriting genes associated with earlier pubertal timing from fathers, which also dispose fathers toward parental absence. Active rGE involves niche selection. For example, adolescents who

have heritable characteristics that dispose them to deviance may self-select into deviant peer groups. The association between adolescent deviance and peer-group deviance would be the result of active rGE. Evocative rGEs result when heritable characteristics cause a systematic environmental response. For example, evocative rGE could explain the association between parental hostility and child behavior problems if the heritable component of child behavior problems evokes parental hostility.

Gene-Environment Interactions

Whereas the alternative strategy model focuses on heritable genetic variation, the conditional adaptation model emphasizes gene-environment interaction (Boyce and Ellis 2005). For example, the caterpillar *Nemoria arizonaria* demonstrates a diet-dependent phenotypic polymorphism (Greene 1989). Caterpillars born in the spring feed on oak catkins and develop an external phenotype that resembles the catkins, which provides evolutionarily advantageous camouflage. Caterpillars born in the summer feed on oak leaves instead of catkins since by summer the catkins have fallen from the tree. Caterpillars that eat the oak leaves phenotypically develop to look like oak twigs, which provides a similar camouflage advantage that reflects the seasonal change in the oak tree. Experimentally feeding the caterpillars the out-of-season food also produces the matching phenotype. These caterpillars have evolved a genetic structure designed to respond contingently to an environmental input, which adjusts their developmental trajectory in evolutionarily advantageous ways. In effect, conditional adaptations are gene-environment interactions.

The development of reproductive strategies in humans is another example of a conditional adaptation, although the GxE architecture is less well known. A substantial body of literature has demonstrated a reliable association between father absence and daughters' pubertal timing. Belsky et al. (1991) theorized that this association reflects a conditional adaptation that calibrates female reproductive strategies to match their future

reproductive ecology. Father absence and associated stresses serve as cues that the reproductive ecology is one where paternal investment is unreliable and/or unimportant. Earlier pubertal timing is a facet of an overall life history strategy that optimizes fitness through a phenotype characterized by early reproduction, unstable pair bonds, and relatively lower parental investment. It is important to note, however, that this association may actually represent a gene-environment correlation and not conditional adaptation, although some research has found fathering effects on girl's reproductive behavior using research designs that control for this confound (Tither and Ellis 2008; Ellis et al. 2012).

Epigenetic Modification

In order for a gene to influence cellular functioning, it must be expressed. Genetic expression involves a process where DNA segments in the cell nucleus – genes – are “read” by transcription factors, and a copy of the DNA segment is replicated into messenger RNA (mRNA). This process is called transcription. The mRNA carries the information out of the cell nucleus to the ribosomes where the protein encoded by the gene is created. This process is called translation. Epigenetic modifications alter the RNA transcription process, and the resulting epigenetic effect serves to turn up or turn down gene expression, upregulating or downregulating the gene like a dimmer switch turns up or down a light.

Epigenetic modification refers to changes *to* DNA (and its chromatin environment) as opposed to changes *in* DNA. The prefix “epi-” means above, on, or over, and epigenetic modifications mean changes to DNA that do not involve modifications to the actual DNA sequence. For example, the most commonly studied form of epigenetic change is DNA methylation, which occurs when a methyl group is added to a DNA sequence. When the methyl group is added in the promoter region of a gene, methylation turns down the gene by reducing, or even silencing, RNA transcription. There are no changes to the DNA sequence itself, only the gene's ability to

produce encoded proteins as well as non-protein-coding RNA (which do not encode proteins but are involved in many forms of genetic regulation).

Molecular Mechanisms for Conditional Adaptation. The hallmark of heritability studies is variance partitioning into genetic and environmental components. This approach assumes that genes and environments have independent main effects on a given phenotype (gene plus environment). This approach statistically quantifies the relative contributions of genotype and environment to phenotypic variation in a population. From a biological point of view, the separation between genome and environment is less well defined since the genome does not operate independently from the environment (Meaney 2010).

From the vantage of conditional adaptation, epigenetic DNA modification may serve as the mechanism through which conditional phenotypes are expressed. If humans have evolved to “detect and encode” relevant environmental information that adaptively entrain developmental trajectories, epigenetic change that results in differential gene expression across environments is a likely mechanism for the development of these phenotypes. Initial research in this area supports this idea. In particular a large body of research in animals (and emerging research in humans) indicates that early life adversity in the form of low maternal care, such as low maternal licking and grooming in rats and mice, increases methylation of the promoter region of the glucocorticoid receptor gene (*NR3C1*) in hippocampal neurons. This results in reduced glucocorticoid receptor expression in hippocampal neurons, stronger and more prolonged hypothalamic-pituitary-adrenal responses (glucocorticoids) to stress, and more fearfulness and defensive behavior against intruders (Meaney 2010). Variability in stress responsivity is hypothesized to be a conditional adaptation (Boyce and Ellis 2005).

Low licking and grooming also results in increased estrogen receptor alpha expression in the anteroventral periventricular nucleus of the hypothalamus and reduced estrogen receptor alpha expression in the medial preoptic area of the hypothalamus. These changes in gene expression regulate development toward faster life

history strategies: earlier onset of puberty in females, more play fighting in young males, greater sexual attractiveness/proceptivity in females, higher rates of pregnancy following mating, and less parental investment in their own offspring (reviewed in Ellis 2013).

The Missing Heritability Problem

Twin studies reveal that, across all traits, average heritability is approximately 50% (Polderman et al 2015). Although additive genetic effects inferred from latent variable models can account for approximately half the differences between individuals on a given trait, heritability estimates can vary substantially across traits. For example, as noted above, height heritability is approximately 80% whereas heritability for a complex trait like education attainment is approximately 20% (Okbay et al. 2016). These heritability estimates suggest that 80% and 20% of the variability in height and education attainment, respectively, can be explained by additive genetic effects (i.e., narrow sense heritability).

Advances in genomics have permitted researchers to examine associations between measured genetic polymorphisms and behavioral and psychological outcomes. The prevailing methodological approach to the study of genotype-phenotype relations are genome-wide association studies (GWAS). In GWA studies, hundreds of thousands to a million or more single-nucleotide polymorphisms (SNPs) are genotyped across chromosomes for every individual studied. Data are also collected on the phenotype of interest, often measured as a binary case/control (disease or no disease) outcome, such as depression diagnosis. A correlation is calculated between each SNP and the phenotype and a stringent multiple testing correction is applied to the statistical significance test, typically $p < .05 \times 10^{-8}$ ($p < .00000005$). The stringent p -value necessitates very large samples, on the order of tens of thousands, to achieve power high enough to meet this statistical criterion. Those SNPs with p -values below threshold, and which replicate, are considered meaningful for the phenotype, although the

GWAS approach is agnostic to the genomic function of a SNP or its causal relation to the phenotype.

GWA studies are a powerful method for gene discovery, however, they have fallen well short of identifying the magnitude of variance heritability studies attribute to genes. For example, GWA studies on height explain about 5% of the variance (Manolio et al. 2009). Similarly, a highly powered GWA study of education attainment explained only about 3% of the variance (Okbay et al. 2016). The discrepancy between variation explained by additive genetic effects in heritability studies and variance explained in molecular genetic studies is known as the missing heritability problem. If heritability studies suggest a large portion of phenotypic trait variation can be explained by genetics, why do molecular genetic studies fail to explain similar amounts of variance? Several explanations have been offered to account for the missing heritability. One class of explanations is methodological. These include imprecise phenotype measurement, questionable comparability between case and control groups, incomplete coverage of all phenotypically relevant polymorphisms, excluding rare variants (<1% frequency), excluding other DNA variations not captured by SNPs, failure to include causally related SNPs, and differences across genetic ancestry (e.g., European vs. non-European). Another set of explanations center on the accuracy of heritability estimates that assume only additive genetic variance contributes to a phenotype (i.e., narrow sense heritability). Heritability estimates may be inflated by nonadditive components, and omitting these sources of variability (i.e., broad sense) in molecular genetic studies may help to account for the missing heritability. More recently, a statistical technique called genome-wide complex trait analysis (GCTA) has been used to estimate heritability using genomic data. Heritability estimates of height, for example, using GCTA have come much closer to accounting for the missing heritability between molecular genetic studies and family studies. However, similar to family studies, this approach assumes nonadditive genetic variation is zero and statistically quantifies genetic variation as a percentage of variance explained. As a result, and similar to

family studies and GWAS, GCTA is limited in terms of identifying causal genetic variation. Importantly, the accuracy and reliability of heritability estimates using GCTA has been criticized based on mathematical and conceptual grounds and therefore may represent large overestimates of heritability (Kumar et al. 2016a, b; Yang et al. 2016).

Conclusion

Genetic inheritance can pose a problem for hypothesis testing from life history theory that posits adaptive phenotypic plasticity such as conditional adaption. In particular, alternative strategies and gene-environment correlations should be considered as possible explanation for conditional adaptation hypotheses and/or methodologically or statistically controlled. The issue of genetic inheritance in life history theory also has parallels with differences between broad and narrow sense heritability where the former captures conditional adaptations by virtue of gene-environment interactions. Because conditional adaptations are gene-environment interactions, this line of thinking and research could help explain the missing heritability problem by evaluating conditional gene-phenotype associations and potential underlying epigenetic mechanisms.

Problem Solving

Shameem Fatima
COMSATS University Islamabad, Lahore,
Pakistan

Synonyms

Complex problem solving; Problem solving ability; Social problem solving

Definition

A problem is a condition that needs to be resolved to achieve a desired goal. Problem-solving makes use of higher order cognitive processes that regulate lower order mental processes to achieve the

goal. Problem solving ability is a person's capability to transform the problematic condition to the goal state by using higher cognitive functions.

Introduction

The whole life involves problem solving from small scale to large scale problems, from simple to complex problems, and from personal and psychological to social, environmental, and collective problems. Problem solving in all problems involves three components: givens (facts or stimuli presented), goals (desired ending), and operations (methods or techniques to achieve the desired objective). Commonly, we engage in problem solving to overcome hindrances, to accomplish a goal, or to find a solution to a problem that has no readymade solution available. The mechanism of converting the given problem situation into the desired goal state is described as problem solving (Lovett 2002). Solutions to most of the problems are generally situation or context specific. Problem solving process usually starts with problem identification and representation, strategic planning and generating solutions, and then, enactment of the most suitable plan to solve the problem. Therefore, the way we understand a problem largely affects the way we solve the problem.

Historically, the early work on problem solving can be rooted back in experimental studies conducted by proponents of Gestalt school in early twentieth century (e.g., Duncker 1935). According to this approach, efficiency of problem solving depends on how much appropriately it is represented in mind. Effective problem solving in insight problems requires an individual to perceive the problem as a whole. Then, ultimately the success of problem solving depends on effective restructuring and reorganization of this representation. Gestaltists propose that problem solving involves closure of a problem because by appropriate representation and closure, an incomplete problem question is resolved towards a complete solution.

However, Behaviorists view problem solving as a process that develops gradually as a result of

positive and negative reinforcement mechanisms. The process also involves trial and error methods. Cognitive psychologists view problem solving as a process involving introspection, observation, and the development of heuristics. A subsequent approach is an information processing approach which proposes that problem solving is a process involving construction of a problem space and then, developing a path through the problem space to resolve the problem (Novick and Bassok 2005). A problem space according to this approach is a universe comprising an original state, all the possible actions and constraints applied to the solution, and an end state. This viewpoint has been quite successful in solving well-structured problems.

Types of Problems

Generally, the problems can be categorized into two categories: (i) *well-structured problems* and (ii) *ill-structured problems*. A well-structured problem is one which has a clear path to a specified solution, though not necessarily a simple and easy path. These problems commonly include formalized, formalized, analytical, and domain specific problems such as presented in disciplines including algorithms, mathematics, etc. They also include isomorphic problems, which have similar formal structure but different contents. Usually, such problems have clearly described given states, set of operations or rules, and goal states. Examples of such problems can be a chess game, a Rubik's cube, and towers of Hanoi game. As well-defined problems have clearly defined given and goal states as well as set of operations so these problems can be efficiently solved by computers. An ill-structured problem, on the other hand, is a problem that does not have a clear path to a solution. Such a problem also does not have a specified set of rules to solve the problem and a specified goal state. Problems involving creativity can be categorized as ill-defined problems. Nevertheless, such problems may involve subproblems that can be well structured.

Additionally, two related forms of problem solving can be described including complex problem solving and collective problem solving.

Complex problem solving involves a collection of creative abilities and knowledge, a broad set of strategies, and self-regulated cognitive processes to solve ill-defined problems. *Collective problem solving* can be described as a problem solving process that is accomplished collectively for problems which are of collective nature such as social and global issues. Such global and collective problems can only be solved at collective level because complexity of such problems exceeds the cognitive limits of a single individual requiring a variety of collaborative and collective but complementary efforts.

Problem Solving Strategies

Problem solving process involves a use of different problem solving strategies. A strategy is described as a plan of operations which can be performed to get a solution to a problem. Various strategies can utilize various actions plans in the way to achieve goal state. The following techniques are usually called strategies: (i) *Trial and Error*, a well-known and commonly used strategy, involves trying many possible plans until the correct solution is sought; (ii) *Algorithm* as a strategy is a formula or a set of step-by-step directions which can be used to solve usually analytical problems; (iii) *Analogy* involves applying an existing solution from an analogous problem to a problem at hand; (iv) *Abstraction* involves trying a solution of problem on similar models of a system before applying it to the real system such as doing psychological experiments on animals; (v) *Heuristic* is another strategy that provides a general framework to solve a problem. It may include mental short cuts or working backward starting from a desired goal. Using heuristics may save an individual's time, effort, and energy in problem solving, but it does not necessarily result in the best solution of a given problem; (vi) *Reduction* is converting a problem into another form for which existing solutions are available; (vii) *Hypothesis testing* involves proposing a probable solution to a problem and then trying to assess it; (viii) *Means-ends analysis* involves selecting and implementing an

appropriate action plan at each step to get closer to the goal; (ix) *Brainstorming* is an important strategy particularly important for collective problem solving which involves generating a large number of solutions by all or many members of a group and then, combining them until the best solution is developed; (x) *Divide and Win* is decomposing a large and complex problem into small, simple, and solvable tasks to get it done; and (xi) *Lateral thinking* involves developing a solution to a problem through indirect and creative means.

Specific use of a strategy varies according to type and importance of a problem, constraints, or the access of information. The problems that have only one specified solution such as mathematical and algebraic problems may involve algorithms and analogies. Other problems that can have multiple goal states and can be solved using multiple sets of operations in one or another combination may use different strategies. Still another category includes problems that can have solutions which change frequently depending on temporal personal, emotional, socioeconomic, and cultural factors, for example, choosing a favorite color on a festival or a present for someone for Christmas. Such problems may rely on heuristics of other logical strategies.

To understand problem solving skills, it is important to note that some problems, particularly analytical ones which are related to specific disciplines such as mathematics or natural sciences may require domain specific skills (Sugrue 1995), while other ones may require general but higher order mental capacities to for its solution (Funke 2001). However, the general complex mental capacities are more important than domain specific skills for a variety of problems in that they assist in better representation of a novel problem situation, which can be useful for generating solutions.

Problem Solving Methods

Problem solving always involves a cycle of step by step directions to solve problems. Generally, these steps include to identify the problem, to

define and represent the problem, to plan a solution, to implement the solution, to review the usefulness of solution, and to revise if needed. Still, many researchers have devised their own specific methods of problem solving. One of such models is a GROW model (Goal, Reality, Options, and Way forward) that is a four-step method to assist a problem solver in structuring problem solving process. Different variants of this model are now available including Goal, Current Reality, Options (or Obstacles), Will (or Way Forward). Another model is the OODA loop (Observe, Orient, Decide, and Act) which involves a decision-making approach to problem solving. The model guides to initially focus on accessible information, then, to filter the information and organize it, and finally, to make the most suitable decision regarding solution. Similarly, PDCA (Plan, Do, Check, and Act), a four-step procedure, is typically implemented in business and management disciplines for continuous improvement of products. Another model is Root Cause Analysis (RCA), which is a more systematic procedure to identify the causes of a problem and to eliminate these causes along with solving the problem. Finding and resolving a way to prevent the problem is the basis of this model. Additionally, a Hive Mind method or a group mind may refer to shared or collective intelligence to solve collective problems. The approach is most commonly used in social psychology and philosophy.

Additionally, there are other problem solving methods which are used in different disciplines including: (i) How to Solve It (understand, plan, carry out plan, and look back to review), which is used in solving mathematical problems; (ii) Eight Discipline Problem Solving (8Ds) is a model developed by a motor company and is typically used in engineering related disciplines; (iii) RPR (Rapid Problem Resolution) is a problem diagnosis model developed to determine the causes of IT related problems; (iv) a Structured A3 problem solving method that is commonly used by manufacturing workers to solve problems; and (v) System Dynamics is a computer-aided problem solving approach to policy analysis and design.

Obstacles and Aids in Problem Solving

There are many factors that can hamper or facilitate problem solving. First, a *mental set, entrenchment, or fixation* that describes an existing and fixed frame of mind to represent a problem, its context, or set of operations to solve it. If an individual has an entrenched mind set, he fixates on a commonly used problem solving strategy that may work well for many problems but may not work for a particular novel problem. Mental sets can also hamper problem solving for routine problems. Stereotypes, an aspect of social cognitions, are also a form of entrenched mental set which may impede generating novel ideas regarding a particular group of objects, persons, or functions. Stereotypes develop in childhood years (Seguino 2007) and usually develop in the same way as other entrenched mental sets develop.

Second, *functional fixedness* is another related hindrance in problem solving that can be described as fixation on a specific use of an object. More precisely, functional fixedness can be defined as an individual's inability to recognize that a particular object that is known to have a particular use can also be utilized for other functions (German and Barrett 2005; Rakoczy et al. 2009). Functional fixedness inhibits an individual from solving novel problems by using existing apparatuses in novel manners. By breaking the functional fixedness, people have become able to use coat hangers to open the locked car and credit cards to open spring locks.

Negative and Positive Transfer as a form of particular mental set may also impede or facilitate problem solving by carrying over already learned strategies to novel problems (Gentile 2000). Transfer of knowledge and skills can be positive or negative. Negative transfer happens when skills and strategies used to solve earlier problems may make it difficult to solve later problems. For example, an individual when presented with a new apparatus tries to operate it in a way he/she is already familiar with (Besnard and Cacitti 2005). Positive transfer occurs when a solution from an earlier problem facilitates solving a new problem (e.g., Campbell and Robert 2008). For example, car mechanics may generalize their

earlier strategies and skills to resolve related problems of different types of vehicles. Positive transfer also involves Transfer of Analogies where a solution from an analogous problem is applied on a new problem. However, transfer of analogies involves an *Intentional Transfer*, that is, the problem solver looks for analogies by recognizing the association between the earlier problem and the new one (Gentner 2000). It is important to note that similarity in content is less important than the similarity in structural systems between two problems in perceiving analogies.

Incubation is an aid to problem solving. For solving complex problems, what is important is to avoid obstacles due to negative transfer rather to look for analogies for positive transfer. Incubation means to set the problem aside for the time being and to take a break from problem solving process. During incubation, the problem solver does not consciously think about it to minimize interference due to negative transfer. However, problem solving process may occur at a subconscious level. Few early investigators have declared incubation to be an important stage of problem solving (e.g., Cattell 1971). However, a recent meta-analysis has reported that incubation is beneficial when individuals have more time for problem solving compared to the situation when individuals are occupied with highly cognitively taxing tasks. Also, incubation works well with divergent-thinking tasks compared to convergent thinking tasks (Sio and Ormerod 2009).

Neuropsychology of Problem Solving

Since the last few decades, neuropsychology has become a rapidly growing area of cognitive psychology focusing on neuropsychological abilities underlying all human behavior. Executive cognitive functions being very important components of neuropsychological abilities have been studied vastly. Executive cognitive functions are higher order cognitive and self-regulatory processes which control fundamental cognitive processes. Problem solving has been described to be one of these executive functions. These executive functions include inhibition, initiation, switching,

problem solving, planning, judgment, and decision making. These higher regulatory abilities are thought to be regulated by frontal areas of brain and particularly, by the prefrontal cortex.

Various studies have found that planning is an essential component of problem solving cycle (e.g., Gunzelmann and Anderson 2003). Planning makes problem solving an efficient and time saving process. As the frontal lobe and prefrontal cortex are described to regulate high regulatory processes, so these areas also play a crucial role in planning during problem solving process. Many brain imaging studies using functional MRI and positron emission tomography scans have reported activation in both the right and left prefrontal regions during the planning phase (Newman et al. 2003) and in frontal lobe during problem solving process (Unterrainer and Owen 2006). The same is described by other researchers studying patients with traumatic brain injury who described that the patients with least damage to the prefrontal areas performed best on problem solving tasks (Catroppa and Anderson 2006; Cazalis et al. 2006). On the other hand, patients with damage to prefrontal areas show difficulty switching from one problem solving strategy to another. Nevertheless, the detailed description of neuropsychology in problem solving is quite complicated and a single brain region cannot be attributed to this complex cognitive function. Rather, it is likely that several brain regions would work in coordination to perform a complex problem solving task.

Problems of Assessing Fertility

Talia Shirazi and David A. Puts
Department of Anthropology, The Pennsylvania State University, University Park, PA, USA

Synonyms

Daily conception risk; Daily fecundability;
Menstrual cycle phase; Ovulatory cycle phase

Definition

A multitude of methods are used in evolutionary psychology research to assess women's menstrual cycle phase and/or fertility, each of which possesses advantages and disadvantages.

Introduction

Of long-standing interest for family planning purposes, the measurement and detection of women's fertility and ovulation have recently approached the forefront of evolutionary psychology research. According to the ovulatory shift hypothesis, women undergo a suite of adaptive physiological, behavioral, and cognitive changes across phases of the ovulatory cycle. While several recent meta-analyses have suggested the robustness of such ovulatory shifts (Gildersleeve et al. 2014a, b),

others have challenged their existence (Wood et al. 2014) and have attributed positive findings to imprecise and elastic procedures used to define fertility (Harris et al. 2014).

It is now well established that the probability of an act of intercourse resulting in conception is nonzero on the day of ovulation and on the 5 days prior (Masarotto and Romualdi 1997; Stirnemann et al. 2013; Wilcox et al. 1995). However, the best way to detect this “fertile window” remains equivocal. Transvaginal ultrasound affords a direct and unambiguous measure and is widely considered the gold standard for fertility assessment, but it is both time and cost intensive, rendering it impractical for many research purposes. Consequently, studies often employ indirect measurements of fertility using methods that fall broadly into three categories: measures relying on observable physiological changes, counting methods, and hormonal methods. Briefly reviewed here are the relative strengths and weaknesses of these different methods of fertility assessment, as well as how they have been applied in evolutionary psychology research, and conclude with methodological recommendations for future work on ovulatory shifts in behavior and cognition.

Physiological Measures

Basal Body Temperature (BBT)

Daily monitoring of BBT has long been used clinically to assess fertility and may be considered the oldest clinical method of fertility monitoring (Lynch et al. 2006). As the corpus luteum is formed after ovulation, it begins releasing large quantities of progesterone into the periphery, resulting in a concomitant increase in BBT of about 0.5 °C. As the increase in BBT is observed after ovulation, BBT monitoring can help retrospectively, though not prospectively, assess timing of ovulation. Epidemiological studies have found that, with little training, women are able to accurately measure their BBT, making BBT monitoring a feasible and valid method of fertility monitoring in large-scale studies. Though BBT monitoring is accurate, easy, and

inexpensive, BBT itself is influenced by many factors that may render BBT readings inconclusive. Psychological and behavioral variables such as stress, changes in sleep patterns, or alcohol use can all substantially affect BBT, leading to fluctuations unrelated to fertility status. Additionally, a small portion of women do not exhibit cyclic fluctuations in BBT during cycles when ovulation occurs.

Cervical Mucus Monitoring

The cervical mucus monitoring method of ovulation detection relies on observed changes in the frequency and consistency of vaginal discharge (Billings et al. 1972). Approximately 6 days before ovulation, rises in estrogen lead to increased cervical mucus secretion, with mucus being sticky or slippery in consistency. Cervical mucus monitoring has been shown to accurately estimate the fertile window when cross-validated with transvaginal ultrasound, LH surges, and plasma estrogen levels, and women can typically be trained to the method in about one cycle of teaching. However, women's hesitations about cervical mucus monitoring may yield it problematic for use in large-scale research studies. While women do not report discomfort or hesitation about BBT monitoring and urine collection for fertility assessment, a significant percent of women express such concerns about cervical mucus monitoring. Additionally, women have reported that the method is uncomfortable and difficult to use (Wright et al. 1992).

BBT and cervical mucus monitoring are often used concurrently for family planning purposes and are together referred to as the sympto-thermal method. Formal analyses have estimated the probability of unintended pregnancies using the sympto-thermal method to be around 2%, suggesting that women are able to accurately monitor their fertility in the great majority of cases (Frank-Herrmann et al. 2007). Nevertheless, due to the training required for such measures and the high drop-out rates associated with the discomfort or unwillingness to use them, these physiological measures are not ideal for fertility assessment in laboratory-based studies.

Counting Methods

Counting methods of assessing ovulation rely on inferences about the lengths of the follicular and luteal phases, as well as the length of complete cycles to determine the timing of the fertile window. To pinpoint this window, forward-counting methods use the starting date of a woman's last menstrual cycle and estimates of the length of the follicular phase, whereas backward-counting methods use the anticipated date of a woman's next menstrual cycle and estimates of the length of the luteal phase. While most studies have categorized women's fertility according to whether women were estimated to be in versus out of their fertile windows, some studies have used counting methods to assess fertility continuously. This is accomplished by assigning conception risk values according to estimated cycle day and published daily conception risk values from the medical literature. Continuous measures have been shown to be significantly more valid than discrete measures, affording greater statistical power (Gangestad et al. 2015). A third way in which counting methods have been utilized has been to assign hormone levels to each day based on estimated cycle day and published average daily hormone concentrations (Garver-Apgar et al. 2008; Puts 2006). Counting methods have been overwhelmingly the method of choice for estimating fertility in ovulatory shift research, with use in over 90% of studies published before 2010 (Gonzales and Ferrer 2015). While such methods are arguably the easiest and cheapest to employ in research, they rely on several assumptions that pose significant challenges to their accuracy.

Both forward and backward counting rely on women's self-reports of their average menstrual cycle length. Studies typically exclude women with reported average cycle lengths that deviate considerably from 28 days and women who report high variability in cycle lengths. Even with such exclusions, the accuracy of self-reported menstrual cycle length is uncertain. Almost half of women will have a cycle range of 7 days or more, and 20% will have a cycle range of 14 days or more across just four cycles (Creinin et al. 2004). It is unclear

whether women are able (Creinin et al. 2004) or unable (Small et al. 2007) to accurately report their average menstrual cycle length, but average cycle length correlates poorly with the length of any individual cycle (Creinin et al. 2004; Small et al. 2007). The accuracy of self-reports may also be moderated by age, such that women under 25 are almost three times as likely to be inaccurate in such reports compared to women 30 and above (Small et al. 2007). This is particularly problematic, as the majority of cycle shift studies are comprised of undergraduate women younger than 25. A second cause for concern is between-cycle variability in the lengths of menstrual cycle phases among regularly cycling women. Follicular phase length may be more variable than luteal phase length between cycles, with a third of women experiencing follicular phase length differences of 7 days or more across cycles, compared to about 9% of women exhibiting this variability in luteal phase length (Fehring et al. 2006).

A great deal of attention has recently been drawn to whether counting methods are accurate estimators of fertility. Two separate studies have reported that when using counting methods to define the 6-day fertile window, around 40% of the days in this presumptive fertile window are actually non-fertile (Blake et al. 2016; Eisenbruch et al. 2015). As much as 60% of the days in the fertile window may be misclassified if forward-counting methods are used (Blake et al. 2016). Such inaccuracies considerably weaken the power to detect true shifts in behavior and cognition during the fertile window. Backward-counting methods seem to outperform forward-counting methods (Gangestad et al. 2015; Gonzales and Ferrer 2015) and thus are associated with less dramatic reductions in statistical power, though when using a between-subjects design and expecting a moderate effect size, backward-counting methods may require 50% more subjects than hormonal methods to achieve the same power (Gangestad et al. 2015).

Hormonal Methods

Luteinizing Hormone (LH) Measurement

LH was first discovered as a valuable measure of fertility through a large-scale study led by the

World Health Organization with the goal of identifying urinary hormone markers of fertility (1983). Though estrogen and LH are typically part of a negative feedback loop during the early follicular phase, as ovulation approaches and levels of estrogen rise, this becomes a positive feedback loop, with increasing levels of LH accompanying increasing levels of estrogen (Hall 2004). During ovulatory cycles, a sharp urinary LH surge is observed between 24 h and 48 h prior to ovulation, making the LH surge a reliable marker of peak fertility and its absence a reliable marker of anovulatory cycles, which are typically observed in about 30% of cycles in undergraduate women (Cantu et al. 2014). As increasing levels of LH are limited to the 24–48 h before ovulation, LH levels can be used to detect earlier days in the fertile window only retrospectively.

Many tests measuring urinary LH are commercially available and are affordable (currently, about US\$0.50 per stick), accurate, and require little training to use, making such tests an attractive method for detecting fertility in research. It is then unsurprising that the majority of studies that have used hormonal measures of fertility in evolutionary psychology research have used LH tests rather than other hormonal measures (e.g., Cantu et al. 2014). While daily LH tests on each day of the menstrual cycle would identify virtually all LH surges, LH tests limited to 9–19 days prior to the anticipated start date of women's next menstrual cycles identify over 93% of all LH surges (Blake et al. 2016). Clear LH surges, however, are not always evident, even in cycles where ovulation does occur. Whereas about 5% of cycles in (non-undergraduate) women in their 20s and 30s are expected to be anovulatory cycles, 25–30% of such cycles lack a clear LH surge (Baird et al. 1991). Thus, while LH surge detection may be the most widely used hormonal biomarker of ovulation, its use in cycle phase studies, which are most often conducted with female undergraduate participants, may yield unacceptably many ambiguous data.

Estrogen-to-Progesterone (E/P) Ratio

The least common method of detecting fertility in recent cycle phase studies is E/P ratio

measurement – in one recent meta-analysis, only one study reviewed utilized E and P measurement to detect ovulation (Gonzales and Ferrer 2015), though several other studies not included in this meta-analysis have utilized E and P measurement as well (e.g., Puts et al. 2013; Bossio et al. 2014). Estrogen is released by the follicle during the late follicular phase, while progesterone levels stay low, resulting in a high E/P ratio. This ratio drops quickly after ovulation, when estrogen levels decrease and the corpus luteum releases progesterone into the periphery. An algorithm using the urinary E/P ratio was originally proposed by Baird et al. (1991) and was able to detect ovulation within 2 days of the LH surge in 88% of cases. Furthermore, the algorithm was able to detect ovulation for 90% of cycles that did not exhibit clear LH surges, suggesting the algorithm may yield more interpretable samples than would LH measurement alone.

Urinary measurement of steroid concentrations, however, has several limitations. First, urinary concentrations represent average concentrations over longer periods of time than salivary or blood concentrations. Second, urinary concentrations represent a combination of both SHBG-bound (i.e., not bioactive) and unbound steroid. Greater than 90% of estradiol and testosterone are SHBG bound, making the majority of the measured steroid in urinary samples of unclear relevance in determining the influence of hormone concentrations on behavior. By contrast, salivary steroid concentrations are more sensitive in that they represent concentrations at the time of measurement itself, rather than an average concentration over a longer period of time. Additionally, the amount measured is limited to bioactive, unbound steroid, affording researchers the ability to investigate relationships between changes in behavior and cognition and the amount of steroids that could be related to these changes (rather than the total amount of steroid).

Conclusion

Evolutionary psychology's increased interest in ovulatory shifts in behavior and cognition, as well as in the effects of ovarian hormones on

behavior and cognition more generally, have resulted in scrutiny of how fertility is assessed. Of the three recent large-scale studies tackling the issue of how fertility should best be defined (Blake et al. 2016; Gangestad et al. 2015; Gonzales and Ferrer 2015), all have provided a similar recommendation for the field moving forward: hormonal methods of fertility assessment should be favored as they are indisputably more precise than other physiological measures and counting methods in detecting women's fertile windows. Comparison of the percent of studies using hormonal methods of fertility assessments published before and after 2010 (7.5% and 11.1%, respectively; Gonzales and Ferrer 2015) suggests that researchers are increasingly perceiving the utility of such methods, and it is likely that this trend will continue in light of recent studies highlighting their advantages. Hormonal methods of fertility assessment that involve measuring ovarian steroids (estrogens and progestogens) afford a second significant advantage: any fluctuations in behavior and cognition across the menstrual cycle are likely to be driven by fluctuating ovarian steroid hormones; however, as so few studies have measured bioactive ovarian steroids, the contributions of individual hormones remain elusive despite over two decades of scientific interest in the topic.

Multilevel selection theory

Definition

Arguments, examples, and alternative explanations that refute group selection theory.

Introduction

Group selectionists argue that it is possible for certain adaptations to evolve because they benefit the group as opposed to benefiting the individual or gene. This has led to arguments in favor of the notion that some cooperative behaviors may have evolved because they have led to the survival of the group. However, critics of this theory have provided many refuting arguments and examples against group selection, as well as alternative explanations for the evolution of cooperative behaviors. This entry discusses these arguments, examples, and alternative explanations.

Alternative Explanations for Group Selection

George Williams (1966) noted that although group selection is theoretically possible, it is unlikely to be a strong evolutionary influence in the natural world. This is because natural selection in favor of the individual will often supersede any selection in favor of the group. Buss (2012) provides the following example, “Imagine a bird species with two types of individuals – one that sacrifices itself by committing suicide so as not to deplete its food resources and another that selfishly continues to eat the food, even when supplies are low” (p. 14). The selfish birds are more likely to survive and reproduce than the suicidal birds who may die before ever passing on their genes. This illustrates that selfish behavior that favors individual selection will have a stronger evolutionary influence than the cooperative behaviors that favor group selection.

Although cooperative and altruistic behaviors are frequently observed in the animal kingdom – even behaviors in which an altruist sacrifices him-/herself to benefit the group – these behaviors are usually explained by theories of individual

selection and/or gene selection. For instance, one of the tenets of kin selection theory (Maynard Smith 1964) argues that individuals are more likely to risk their lives to rescue kin as opposed to nonkin. This is because altruistic behaviors may be caused by a particular gene, and although the altruist may perish during the altruistic action (such as saving a sibling from a burning building), that gene may still be passed onto the next generation through the reproduction of the surviving kin member – because the altruist had that particular gene, and the recipient is related to the altruist, there is a certain probability (depending on how closely related the altruist and recipient are to each other) that the recipient also has a copy of that altruism gene (Park 2007). Therefore, a sacrificially altruistic behavior, which appears to have been conducted for the benefit of someone else in the group, may actually have been performed for the benefit of the gene responsible for that behavior.

Similarly, just because an individual foregoes his/her own reproduction to benefit the overall group does not mean that his/her sacrifice is adequately explained by group selection. For example, some adult male jackals will stay with their parents to help raise future litters of their younger siblings. These jackals often do not reproduce, but their presence significantly increases the survival rate of the future litters, allowing for the male jackal’s genes to still be passed on indirectly via his siblings (Moehlman 1987). Although this cooperative behavior increases the survival of the group, it persists because it also increases the reproduction of the individual’s genes – indicating that this behavior is influenced by natural selection at the genetic level, not the group level.

Reciprocal altruism theory (Trivers 1971) is often another alternative explanation for cooperative behaviors that appear to be conducted for the good of the group – such as food sharing among unrelated individuals. Although humans and other animals will often share food with nonkin – indicating that this behavior is not influenced by kin selection – this sharing is frequently conducted between individuals who have a history of sharing. In other words, this sharing occurs on the basis of reciprocity. For instance, vampire

bats will share food with kin and nonkin; however, they will only share their food with the nonkin who have previously shared food with them (Wilkinson 1988). Humans possess similar food sharing behaviors, which have been studied extensively in modern-day hunter-gatherer tribes (Berte 1988; Gurven 2004; Gurven et al. 2001). In short, humans and other animals give food to unrelated individuals so that they may maintain reciprocal relations – allowing them to receive food in times of need. This allows for the successful survival of the individual.

Conclusion

Group selection has provided much controversy over the years with many great scientists each taking opposing sides. Although after Williams (1966) book, group selection was widely rejected in the scientific community. However, in recent years, group selection has seen a resurgence but is now called multilevel selection theory (see entry titled ► “Multilevel Selection Theory” for more information). Although these examples and alternative explanations continue to be used as arguments against group selection theory, proponents of group selection argue that not all cooperative behaviors can be explained by gene selection and individual selection.

Definition

Procedural knowledge is proposed as the system containing memories of how the human brain can proceed to do things.

Introduction

It is argued that physical activities as well as cognitive skills are the outcome result of

procedural knowledge, as they are not expressed through verbal communication but by means of performance. Procedural knowledge is relatively autonomous in relation to declarative memory. This can be argued by the expression of certain types of amnesia such as anterograde amnesia and Korsakoff's syndrome as individuals are no longer able to collect or recollect new declarative facts. Although painful and slower than normal, patients who suffer from amnesia are still able to acquire new procedural skills after the onset of the brain degeneration. Automatic functioning in procedural knowledge is also indicated by the learning procedures an amnesia patient's brain is able to accommodate. Examples of learning in amnesia patients are conditioning, word complementing, and the effect of priming on word recognition. These tasks render vivid implications that procedural skills are proceeded through performance and not by conscious recollection of the experience of the learning process.

Evolutionary Perspective of Procedural Knowledge

In animals the ventral stream of visual analysis is primarily concerned with object recognition. The dorsal stream is concerned not with seeing where but mainly with seeing how. This division bears a strong correspondence to the distinction between declarative and procedural memory (Baddeley 1990). Although the anatomical correlates of these divisions differ considerably, the functional correspondence is striking. These parallels unite a physiological approach with a psychological view on vision and its relation to action upon the environment (Goodale and Milner 1992).

Gibson's Theory

J.J. Gibson (1968, 1979) is the founder of what is canonically called "direct perception." Direct perception is the view that in perception it is not needed to assume that any higher-order processing and internal representations involved in perception. The environment contains sufficient information to give rise to visual perception. The theory of direct perception has been developed in response to serious problems that arose in the

traditional, physical, approach to vision. One of the core assumptions in Gibson's theory is the assumption that the most relevant features an animal perceives are what the world affords an animal to do. Accordingly, what affordances are perceived is unique for each animal. If what is perceived is meaningful, it is meaningful relative to an individual organism. Members of the same species more often perceive the same affordances of objects than individuals of different species. Gibson suggests that the ecological concept of "niche" is to be seen as the set of affordances for an individual member of a species. Because an affordance is not a phenomenal object, it changes as an animal changes, such as developing physical handicaps. However, it does not change as the need of an animal changes. Although Gibson avoided physiological or neurological considerations, it can be inferred that his theory refers to the dorsal stream of visual analysis, and it concerns animals with a cortex, since information stem from procedural memory and it concerns seeing "how" to do things.

Nonhuman Species and Evolvment of Knowledge

Phylogenetically, it can be argued that procedural knowledge is older than declarative knowledge. This can be shown by the fact that declarative learning only occurs in higher animals, if not human beings (Ornstein 1991). Ontogenetically, it is demonstrated by the fact that children begin to learn and remember procedures before they do facts (Bloom and Lazerson 1988). Also, procedural skills are more important for survival than declarative facts (Dudai 1989). Hence, it is not reasonable to assume that knowledge of facts evolved before the knowledge of skills. Another argument has to do with recent developments in the research on neural networks. By their very nature, neural networks are suited for the modeling of procedural knowledge. When an input is fed to a network, it "knows" how to react. This knowledge is implicit and can only be made explicit by the analysis of hidden units. Procedural knowledge is a concept of a dynamic process that cannot be

represented validly by means of a sequential rule system (Bechtel and Abrahamsen 1991). Networks have been designed in a way that are able to assimilate concepts which were traditionally considered to be propositional systems, for instance, certain rudimentary language structures and logical inferences (Bechtel and Abrahamsen 1991). In psychologically relatively plausible systems that operate on these classes of input, propositions are considered as a description of the outcome of a process, not as a description of the process itself.

Conclusion

It has been argued that declarative memory evolved from procedural memory and it constitutes a part of it. Some of its aspects might be reduced to procedural memory. It is both phylogenetically and ontogenetically younger than procedural memory, it is shown to be possible to model declarative knowledge in procedural systems and neural networks, and in some cases, one-trial learning can function within the procedural system. This notion suggests that declarative knowledge is made possible by procedural knowledge; interpretively, declarative knowledge could be considered a special case of procedural knowledge.

Definition

Understanding and reducing the severity and frequency of aggressively dominant behavior.

Introduction

Bullying behavior is ubiquitous in human societies and appears to be a successful evolutionary strategy. However, the damage done by bullies in childhood can be severe. Along with a multitiered approach that involves the intervention of several adults, preventative measures should also encourage alternative prosocial strategies to achieve social goals.

Definition of Bullying

Bullying is a complex social behavior, loosely defined as the intentional use of physical and psychological force or power, threatened or actual, on a one-on-one or group basis against another person, group, or community that often results in injury, psychological harm, mal-development, deprivation, or even death (Krug et al. 2002). All bullying is aggression, but not all aggression is bullying (Hawley 1999). Bullying is a specific type of aggression that is intended to harm or disturb physically or psychologically, occurs repeatedly over time, and includes an imbalance of power with a more powerful person or group attacking a less powerful one (Nansel et al. 2001).

Forms of bullying include, verbal, physical, sexual, social, or racial/ethnic, each serving a particular function, but bullying is generally classified as direct or indirect (Juvonen and Graham 2014). *Direct physical bullying* is physically confrontational, which can involve hitting, tripping, pushing, poking, damaging property, physical threats, giving intimidating looks, stealing property, and touching and/or brushing up against (in a sexual nature). *Direct verbal bullying* can involve insults, name-calling, put downs, laughing at, threatening, sexual innuendo, and verbally abusing a name, family, religion, sexuality, disability, or other individual characteristic of a “target.” *Indirect bullying*, sometimes referred to as “social bullying,” harms someone’s social reputation and/or causes humiliation and is harder to recognize as it’s often carried out behind the targets’ backs (Juvonen and Graham 2014). Indirect bullying can entail lies, spreading rumors, playing nasty jokes to embarrass and humiliate, mimicking, deliberately excluding someone from activities, encouraging others to exclude someone, damaging social reputation acceptance, or deflating social status while concealing the identity of the perpetrator (Bernard and Milne 2008). A new form of bullying involving computers and social media, referred to as *cyberbullying*, consists of being cruel to others by sending or posting harmful material, or engaging in other forms of social

aggression using the Internet or other digital technologies.

Researchers have also identified other types of bullying, like *reactive bullying*, a defense reaction to a perceived threatening stimulus that’s accompanied by some visible form of anger; *proactive bullying*, an unprovoked aversive means of influencing or coercing another person (more goal-directed); *overt bullying*, a confrontational set of behaviors directed towards another individual or a group of individuals; *relational bullying*, a type of behavior that involves excluding someone from a social group, spreading rumors, keeping secrets, or humiliating someone in a social setting (indirect); and *punking*, a practice involving verbal and physical violence, humiliation, and shaming in public (Hong and Espelage 2012).

Prevalence of Bullying

Bullying has been observed in every human society, including modern hunter-gatherers. In a study of 79 different countries, approximately 30% of adolescents reported bullying victimization (Elgar et al. 2015). Multinational studies have found that the most intensive bullying was found in countries where violence and social intolerance are the most commonplace, with the lowest per-capita income (Bernard and Milne 2008; Elgar et al. 2015). In Western nations, an estimated 4–9% of youths frequently engage in bullying behaviors, and 9–25% of school age children are victims of bullying, with a smaller subgroup of bully-victims who both bully and are bullied (Nansel et al. 2001). Bystanders, referring to a viewer, observer, witness, or passerby, can also be indirectly involved in bullying incidents by encouraging fights, cheering the bully, and help the bully by warning them if an authority figure is coming (Hong and Espelage 2012).

Bullying begins in early childhood, where it emerges in almost any group of toddlers playing freely (Hay et al. 2004). Bullying increases over childhood, peaking around the age of 14 (Volk et al. 2012), with 85% of incidents occurring in the presence of peers (Bernard and Milne 2008). Girls are more likely to use teasing, rumors, and taking of personal belongings, while boys are

more likely to initiate bullying and use direct physically aggressive methods (Juvonen and Graham 2014; Nansel et al. 2001). While indirect bullying is more common for girls early on, during middle adolescence indirect bullying, specifically verbal aggression, becomes most frequently used by both genders (Juvonen and Graham 2014; Nansel et al. 2001).

Evolutionary History of Bullying

Dominance and submission are prominent underlying mechanisms that span all cultures (Boehm 2009). The universality of bullying across human societies indicates a species-typical human behavior, deeply rooted in our evolutionary history. Bullying-like behaviors are also found in many animals, including every major group of primates. The expression “establishing a pecking order” often represents dominance achieved through aggression and bullying, which is derived from birds (particularly chickens) that use repeated aggressive pecking to establish social hierarchies (Volk et al. 2012). In chimpanzees, our closest genetic relatives, direct physical aggression can be a strategic behavior, particularly for males who can achieve high social status through physical domination and intimidation that can lead to better access to food resources and mating opportunities.

Hunter-gatherer societies represent the oldest form of human culture, encompassing at least 90% of human evolutionary history (Lee and Daly 1999). The few remaining hunter-gatherers share some commonalities with chimpanzees, such as depending on foraging and living in flexible local groupings, but socially, they are vastly different. Hunter-gather cultures are quite egalitarian, with sharing being a central rule of social interaction, and community sanctions against bullies (Lee and Daly 1999). Social control in hunter-gathers is preemptive, with groups being vigilant about violators of cultural norms and ethics, and frequently using humor to cloak moralistic aggression (Boehm 2009). Bullying outside the family is considered unethical, since it brings about intergroup conflict, and adults line up against deviants who threaten the quality of social life (Boehm 2009). Deviants typically submit to

the group, but for those who don't, negative effects are being ridiculed and criticized, or more consequentially, ostracized and expelled (Lee and Daly 1999). If brain size is a measure of actuarial ability, then socially regulated behavior and moral sanctioning most likely began in the Middle Pleistocene, where notable increases in brain size exist in the fossil record (Boehm 2009).

Motivations for Bullying During Development

Humans have altered the impact of bullying through language and culture, but it is still used as a strategy to obtain valued resources and maintain social order in children and adults alike (Smith et al. 1999, p.16). According to *Resource Control Theory* (RCT), social dominance is a means of positioning oneself near the top of a social hierarchy for access to resources, either material, social, or informational (Hawley 1999). In support of RCT, commonly reported reasons that children and adolescents bully include displaying power, maintaining leadership status, gaining acceptance from or access to a desired peer group, strengthening self-identity, and getting what they want (Bernard and Milne 2008). Bullies can also shape social groups in that they often select out-group targets, which they perceive as unlike themselves in terms of social group and identity. Ultimately, the essential quality that bullies seek in a target is vulnerability, but they tend to focus on targets least like themselves (Bernard and Milne 2008).

There are psychological advantages to being a bully compared to victims and bully-victims. For example, those children who are classified as pure bullies generally report equal or better mental health than bully-victims and pure victims, and in adolescence, bullies are perceived as more popular, socially dominant, and likeable (Volk et al. 2012). Additionally, stronger adolescent boys (who are more likely to engage in bullying and also start dating at a younger age) report greater dating opportunities and likelihood of being in a dating relationship, and bullying behaviors in adolescence have been linked to high social status later in life (Volk et al. 2012).

Even though there are advantages to bullying, such behaviors are displayed overwhelmingly (approximately 90%) by students with low levels of social and emotional wellbeing (Bernard and Milne 2008). Several clinical factors have been associated with bullying (and victimization), including negative adult influences, low parental involvement, negative family interactions, childhood maltreatment, exposure to interparental violence, divorce, association with peers who bully, and neighborhood violence (Hong and Espelage 2012).

Psychological Effects of Bullying on Victims

Even though bullies may suffer from several clinical issues, victims suffer more immediate and long-term consequences, such as depression, loneliness, generalized and social anxiety, and lower self-worth (Volk et al. 2012). Rodent studies indicate that social stress, experienced when one rat repeatedly attacks or takes resources from another, results in heightened levels of anxiety and changes in brain chemistry lasting far after the stress alleviation (Kinsey et al. 2007; Vidal et al. 2011). With children, repeated exposure to bullying undermines their health and wellbeing, leading to anxiety, depression, and other psychosocial complaints. Victimized children and adolescents report ailments such as tiredness, sleep problems, abdominal pain, bedwetting, and suicidal ideation; with boys being four times more likely, and girls eight more times likely, to be suicidal because of bullying (Bernard and Milne 2008). Victims and bully-victims have elevated rates of psychiatric disorders in adulthood, such as generalized anxiety disorder, panic disorder, and agoraphobia, even when controlling for childhood psychiatric disorders and family hardships (Hong and Espelage 2012).

Procedures for Curbing Bullying

Given its prevalence in human cultures and animal species, bullying is a behavior that may never be completely removed from all social

interactions. From an evolutionary perspective, bullying can be seen as a successful strategy to obtain valued physical, social, and reproductive resources. In stable cooperative groups, however, an excess of bullying can lead to serious negative consequences for the social group, the bully, and particularly the victim. Ancient cultures dealt with in-group problems through cooperative efforts; bullying was not curbed simply by one individual, but through a collective reinforcement of social norms (Boehm 2009). Methods do exist to mitigate the frequency and severity of bullying incidents, but just like in older cultures, success depends on a collective and concentrated effort from many agents such as parents, teachers, mental health professionals, and peers.

Parents and extended family members can reduce bullying behaviors through fostering positive relationships with high parental warmth (listening and providing affection), employing authoritative parenting styles (clearly communicated expectations and calmly implemented discipline for poor behavior), and modeling appropriate behavior (displaying assertive skills and emotionally controlled responses) (Bernard and Milne 2008). Teachers can reduce bullying behaviors through behavioral contracts (plans of positive action that help students move towards acceptable behavior), socioemotional education (providing learning experiences in empathy and resilience), and nonpunitive problem-solving meetings (for bullies, victims, and parents) (Bernard and Milne 2008). Peers can be trained to mediate disputes, offer support and friendship, and assist bullying victims through the use of simple counselling skills like listening, showing understanding and support, and converting bullying bystanders to victim defenders (Bernard and Milne 2008; Volk et al. 2012).

While most antibullying programs are often successful in the short-term, they fail to address the root of the problem. Programs like “zero-tolerance” do not have long-term effects, considering they require bullies to stop advantageous behavior (Volk et al. 2012). Successful interventions should focus not just on punitive reactions to bullying, but proactive alternative, prosocial methods of attaining social dominance, as seen in many hunter-gatherer cultures (Hawley 1999;

Lee and Daly 1999; Volk et al. 2012). Although introducing prosocial strategies should be included in bullying prevention, a one-size-fits-all approach should not be used for every situation (Volk et al. 2012). The most effective methods have different tiers of response to children who bully, from teachers equipped with communication skills and interventions, to parents and principals who can employ more intensive interventions, to mental health professionals who can provide mentoring in social-emotional skills and more concentrated individual and family therapy (Bernard and Milne 2008; Volk et al. 2012).

Conclusion

Bullying is a successful evolutionary strategy for many animals, including humans. Dominance and submission are prominent underlying mechanisms that run across all cultures. However, all cultures, including hunter-gatherers, have social sanctions against killing, deceptive lying, theft, incest, and bullying by upstarts, coupled with positive views of altruism and cooperation for maintaining social order and consistency (Boehm 2009). By incorporating a deeper understanding of the evolutionary history of bullying, society can modify policies to increase the wellbeing of children, adolescents, and young adults.

Definition

Males and females produce gametes that are differentially specialized to facilitate the sexes in reproduction.

Introduction

The production of gametes is a biological process occurring in organisms that sexually reproduce. Females make gametes called eggs, and males make gametes called sperm. Both egg and sperm cells begin as identical germ cells and are produced through a process of cell division called meiosis, which reduces the number of chromosomes in the germ cell from 46 (diploid) to 23 (haploid). In human males, meiosis begins after birth, and, upon reaching puberty, men produce sperm continuously for the rest of their lives. In human females, meiosis begins before birth and the raw materials for egg cell production are formed while the female fetus is still within the uterus of her mother. Every female is born into the world with a limited number of egg cells in her reproductive system. These eggs are released one by one (occasionally two at a time) into the uterus at each monthly cycle of ovulation when and after she has reached puberty, and this cycle ceases when she has reached menopause. Fertilization occurs when a sperm cell successfully combines with an egg cell inside the female reproductive system, and this restores the gametes to a diploid with 46 chromosomes in the form of a zygote. The process of gestation then begins and will likely result in pregnancy as the zygote develops into a fetus.

The Evolution of Sex-Differentiated Gametes

To understand the significance and implications of sex-differentiated gametes, it is important to consider how sexual reproduction evolved. This chapter covers the selection pressures that likely led to sperm and egg cells as highly specialized gametes each with their own reproductive interests and how these differences between gametes lead to intrasexual competition and intersexual selection on the part of males and females, respectively.

From Asexual to Sexual Reproduction

Before there was sexual reproduction or sex, organisms reproduced via asexual reproduction,

where all of a parent organism's genes are passed on to its offspring through a process of mitosis, or the division of the mother cell into two genetically identical daughter cells. In contrast, in sexual reproduction, two individual parent organisms are required and only half of each parent's genes are passed on to the next generation. A major constraint of sexual reproduction is that individual organisms must find and coordinate copulation with a conspecific mate in order to reproduce. Despite this significant cost, sexual reproduction dominates among multicellular forms of life, indicating that the gains in fitness to offspring produced sexually have, over evolutionary history, outweighed the costs of sex, especially for more complex life forms. The process of meiosis – recombination of genes from two genetically different parents from the same species – thus underlies the benefits of sex (Maynard Smith 1978).

The recombination of genes through sex provides another avenue besides random mutations for evolutionary adaptations to develop by allowing offspring of each generation to have genetic information and thus, phenotypic traits, that are different from what either parent has. A species that generates greater phenotypic variation can evolve faster in response to selection pressures because with greater variation, more advantageous phenotypes are likely to surface (Zimmer 2009). For instance, when new environmental parasites attack a population of asexually reproducing organisms, the organisms are unlikely to quickly adapt new defenses against these novel parasites as asexually reproducing organisms in the population share the same defense systems that only work against familiar (pre-existing) parasites. On the other hand, the genetic variation of sexually reproducing organisms enables offspring – from genetic recombination – to vary more greatly in their parasitic defense systems, thereby reducing the likelihood that an entire population would be rapidly wiped out from a single novel parasitic attack (Hamilton et al. 1990). Environmental factors therefore serve as useful selection pressures that eventually allow only the fittest organisms (i.e., those that have the most adaptive combination of genes) to survive and reproduce. Further, sexually

reproducing organisms tend to find mates with good genes attractive, leading to different recombinations that, on average, lead to better offspring fitness (Zimmer 2009). Sex therefore creates new gene combinations that can weed out bad genes and propagate good genes.

The Origins of Gamete Dimorphism, or Males and Females

Sexual reproduction occurs in two ways: either through isogamy, which refers to the fusion of gametes of *similar* shape and size, or anisogamy, which refers to the fusion of gametes that *differ* in shape and size. Among sexually reproducing organisms, isogamy is commonplace (but not universal) in unicellular organisms. As the gametes contributed by isogamous parents are similar, they cannot be differentiated as male or female. In contrast, anisogamy prevails exclusively in multicellular animals and plants (Zimmer 2009), and the smaller gamete is considered to be male while the larger gamete is considered to be female. In humans, an egg cell is 85,000 times larger than a sperm cell, and sperm are also produced in much larger quantities than eggs.

Ghiselin (1974) argued from an economic specialization standpoint that anisogamy could have originated from a physiological division of labor, whereby some gametes began specializing in nutritional and material resource provision, thus becoming larger, while other gametes specialized in motility, therefore maintaining a small size and growing tails for propulsion. Parker et al. (1972) also proposed that anisogamy evolved via individual-level selection and competition. Males that produce more (but smaller) gametes stand to gain a larger proportion of fertilizations because they produce a larger number of mobile gametes that can “seek out” the larger gametes. However, because zygotes formed from larger gametes have better survival prospects, this process can lead to the divergence and specialization of gamete sizes into large and small (female and male) gametes. The end result is one where numerous small gametes compete for access to large but scarce gametes that are tasked with providing maximal nutritional and material resources for the offspring (Parker et al. 1972). Males therefore tend toward

achieving “quantity,” while females tend toward achieving “quality” in a bid to increase reproductive success.

Intrasexual and Intersexual Selection Drives Production of Large Numbers of Tiny Sperm to Compete for Access to Valuable Female Gametes

In humans as well as many other anisogamic species, sperm are much cheaper than eggs. Men replenish their sperm at roughly 12 million per hour, while women only have a finite lifetime supply of approximately 400 eggs. This sex difference in the value of gametes is fundamental to psychological, behavioral, and physiological differences between males and females. Trivers’ (1972) theory of parental investment described how the sex with more resources (usually females) evolve to be more discriminant about having sex while the other sex (usually males) evolve to compete for access to the higher-investing sex. As there is an abundance of sperm, the selection pressure shifts for an egg producer to be prudent in choice as it is unlikely that her eggs will fail to find eager sperm. Conversely, the selection pressure shifts for a sperm producer to ensure that the sperm can reach the egg before it is fertilized by numerous other rival sperm. Evolution thus favors selectivity in females to ensure that their limited eggs get fertilized by the best sperm and greater sperm quantity production in males to increase their chances of winning during sperm competition.

In humans, men evolved to be more sexually persistent and have a stronger desire for sexual variety compared to women and to favor a short-term mating strategy in order to increase their access to more sexual partners. These adaptations serve to increase the chances that their sperm can fertilize as many eggs as possible. Women, on the other hand, evolved to be more sexually restricted than men and to prefer a selective, long-term mating strategy (e.g., Li and Kenrick 2006) in order to procure the qualities of one or a very limited few desirable mates (for their good genes, resources, etc.), since being wasteful with their limited eggs would be detrimental to reproductive success (Goetz and Shackelford 2009).

Females are also attracted to the victors of intrasexual contests, and thus men may have also evolved to be more aggressive and stronger than women in order to compete intrasexually with mating rivals (Buss and Duntley 2006).

Sperm competition is another form of intrasexual competition by males and intersexual selection by females for the best genes to be passed on to the offspring (Goetz and Shackelford 2009). As sperm quality and offspring quality may be correlated, a female’s reproductive fitness can be increased when more sperm competition is encouraged. Sperm quality (which pertains to how healthy and mobile the sperm are) and sperm quantity (which differs among males) both serve to signal the fertility of a male and the eventual differences in probability of successful conception. Indeed, in some species, females may mate with multiple males so that the sperm of these males can compete and only the best sperm will achieve successful fertilization of their eggs (Baker and Bellis 1995). Several studies have found that large testes size, hence greater sperm production capacity, is a feature of species that exhibit multi-male mating systems (Shackelford and Goetz 2006). Male reproductive fitness increases linearly with increasing mating encounters (with different females), whereas female fitness increases less rapidly with multiple matings (Trivers 1972; Goetz and Shackelford 2009). These circumstances create evolutionary pressures for males to produce the most and best-quality sperm within their own metabolic constraints to increase the odds that their sperm can fertilize the egg over rival sperm, while scarce and valuable eggs incentivize females to entice sperm competition so that they can be selective of mates with better quality sperm.

Among humans, women sometimes engage in multiple matings to generate sperm competition at some point in their lives, and women are also most likely to multi-mate when the chances of conception are high, indicating that women may (either consciously or unconsciously) schedule their copulation activities to allow the most competitive sperm to fertilize her egg (e.g., Baker and Bellis 1995). Women in contemporary human populations may therefore mate in a

polygamous manner to differing extents across cultures, potentially generating sperm competition in their reproductive tracts (Shackelford and Goetz 2006). Even in purportedly monogamous, committed, and long-term mating contexts, as the proportion of time a couple spends together since their last copulation decreases, the probability that the man's partner has been inseminated by another man also increases. Correspondingly, the longer a couple spends time apart, the greater the volume of sperm the man ejaculates at the couple's next copulation (Baker and Bellis 1995). Therefore, the pressures of sperm competition can further drive the dimorphism of gametes that were initially differentiated through the benefits of specialization.

Conclusion

The reproductive benefits of genetic variation gave rise to the evolution of sexual reproduction, where parents each share half of their genetic material to produce genetically different offspring through meiosis and fertilization of gametes. This process tends to eliminate bad genes and propagate good genes, thereby producing fitter offspring. Further benefits of gamete specialization drive the dimorphism of gametes such that males produce tiny and mobile sperm that specialize in seeking out eggs that specialize in carrying vital nutrients and resources. As eggs are more valuable than sperm, the reproductive success of a female hinges on the quality of the sperm that fertilizes her egg, while the reproductive success of a male depends on the quantity of sperm he can produce, which increases the likelihood that his sperm wins over rival sperm in fertilizing the egg. Reproductive success for anisogamous life forms therefore benefits from sperm competition (i.e., intrasexual competition between the quantity and quality of rival males' sperm and intersexual selection by females of the best sperm among rival males). Taken together, these factors drive the evolution of gametes such that males produce larger quantities of small sperm relative to the large and scarce eggs of females.

Projected Confidence

Victoria Blinkhorn

School of Psychology, University of Liverpool,
Liverpool, UK

Synonyms

[Instil confidence](#); [Self-enhancement](#)

Definition

It is important to be clear on the meaning of projected confidence and how it differs from self-confidence. Self-confidence is personal assuredness in one's own ability or judgment. Projected confidence is the ability to ingrain that confidence onto others; in other words, have others believe in your competence.

Introduction

Following from the previous chapter, this entry focuses on how individuals may use manipulative communication with others via projected confidence in order to protect or enhance their self-esteem. It will also demonstrate how the specific personality construct, narcissism, may accentuate this from an evolutionary perspective.

Self-Enhancement

It could be argued that self-enhancement is the root of projecting confidence onto others. Self-enhancement involves a self-directed effort by an individual to increase the positivity of their public image (Wallace 2011). The personality construct that is most well known for chronic self-enhancement is narcissism. In accordance with the three key evolutionary perspectives discussed in the previous chapter (► [“Self-Esteem as Manipulative Status Communication”](#)), narcissists’ self-esteem is fragile and therefore, their continual self-enhancement is to preserve and protect it (Morf and Rhodewalt 2001).

It is believed that narcissism has evolved in accord with promiscuous mating strategies, or short-term mating, and that it has persisted through specific characteristics related to self-enhancement such as attractiveness and coercive tendencies (Holtzman and Strube 2011).

Attractiveness

Research has found that narcissism is associated with higher observer-rated physical attractiveness (Holtzman and Strube 2010). This is due to the types of behavior narcissists present and how they project this onto others. For example, the attention seeking style of behavior narcissists present may stimulate sexual desire among potential short-term mates. Holtzman et al. (2010) found that narcissists use more sexual words in everyday life, and importantly, this remained the case after excluding those swear words which have a sexual connotation. It seems that in relation to sexual language, narcissists are able to project this type of confidence on to others and that may be one explanation as to why others find them attractive. This is one example as to how a narcissistic individual has a higher chance of attracting a short-term mate. Another example is the exhibitionism they present, a core trait of narcissism. Research has found that narcissists take extra care in their appearance such as wearing expensive clothing (e.g., Back et al. 2010) and females in particular focus on their sexual appearance such as wearing

make-up (Vazire et al. 2008). Again, narcissists can project confidence, via exhibitionism, onto others which contributes to their chances of finding a short-term mate.

Coercion

Narcissism in both males and females has been found to be significantly related to sexually coercive strategies (e.g., Blinkhorn et al. 2015). It is believed that narcissists’ characteristics such as game-playing love styles (Campbell et al. 2002), musculature (Vazire et al. 2008), and disagreeableness (Paulhus 2001) all enhance their chances of successfully coercing another. Displaying this type of behavior is another way in which narcissists can project their confidence onto others. From an evolutionary perspective, it could be suggested that many years ago, narcissists who were less coercive had more difficulty reproducing (Holtzman and Strube 2011), and therefore, this trait has strengthened and evolved to facilitate higher chances of finding a short-term mate.

Conclusion

The personality construct, narcissism, is characterized by self-enhancing types of behaviors such as attractiveness and sexual coercion, in order to project confidence onto others. These behaviors are examples of manipulative communication with others in order to protect or enhance self-esteem. From an evolutionary perspective, it can be argued that narcissistic traits have adapted in order to increase the likeliness of short-term mating. The following chapter will discuss how narcissistic individuals may also manipulate others by the ► [“Derogation of Rivals.”](#)

Promoting Paternity (You Look Like Your Father Phenomenon)

Laureon Watson

Western Illinois University, Macomb, IL, USA

Synonyms

[Facial resemblance](#); [Kin recognition](#); [Parent-child resemblance](#)

Definition

The tendency for mothers and maternal relatives of infants to remark that a child looks like the father more often than commenting on resemblance to the mother.

Introduction

Paternity uncertainty is an adaptive challenge for males, but not for females (Buss 1996). Due to the risk of cuckoldry, a man is less likely to invest in his partner's child if he is less confident that the child is his own (Pagel 1997; Gaulin and Schlegel 1980). Children living with a step-father or adopted father are more likely to be abused or neglected than those who live in a home with their biological fathers (Daly and Wilson 1996). Similarly, women are at greater risk of being abused if some children in the home are not related to their male partners (Burch and Gallup 2000). Because of the potential risk to the health and safety of both women and children in the case of a father doubting his paternity, women may have an evolved tendency to assure their partners of paternity by making comments that attest to the children's resemblance to them. On the contrary, evolutionary pressure may have shaped the appearance of infants in favor of concealing the identity of their fathers, which would protect against abuse or abandonment in the case of cuckoldry (McLain et al. 2000).

Empirical Evidence

In a 1995 study on parent-child resemblance, Christenfeld and Hill found that photos of 1-year-old infants could be matched to photos of their fathers, but not to their mothers (as cited by Christenfeld and Hill 1995; McLain et al. 2000). These researchers suggested that infants may have evolved to closely resemble their fathers as a mechanism to afford paternity confidence and ensure paternal investment. However, other researchers report that infants are more accurately matched to their mothers than to their fathers (Nesse et al. 1990; Brédart and French 1999). Brédart and French (1999) failed to replicate the results found by Christenfeld and Hill (1995) and argued that if the appearance of infants had evolved to reveal paternity, the current degree to which babies resemble their fathers would be much higher than it is. They posited instead that babies conceal their father's identity by more closely resembling their mothers; this would afford protection to the child if the biological father was not the mother's partner. Further, the stronger mother-infant resemblance may be biologically significant; Moore and Haig (1991) provide evidence that genomic imprinting leads to preferential expression of maternal genes in order to allow greater control of resource flow from the mother to the fetus (as cited by McLain et al. 2000).

The pattern of results from these studies suggests that babies tend to resemble their mothers more closely than their fathers. However, as paternity confidence tends to promote greater paternal investment in offspring (Gaulin and Schlegel 1980; Alvergne et al. 2009), mothers and maternal relatives may have evolved a tendency to verbally attest to the likeness of infants to their domestic fathers. Indeed, Daly and Wilson (1982) found that comments on parent-child resemblance made by mothers in maternity wards were biased toward affirming father-child similarity. The comments made by fathers do not share the same bias. This difference suggests that women's comments about parent-child resemblance may have an ultimate purpose of promoting paternity certainty in order to secure resource investment from their male partners.

Conclusion

Though infants may have a tendency to more strongly resemble their mothers than their fathers, mothers may seek to ameliorate the problem of paternity uncertainty, as well as promote paternal investment in the child, by making comments about infants' resemblance to their domestic fathers.

Proprioception

Michael Khalil
University of Nicosia, Nicosia, Cyprus

Synonyms

[Body parts awareness](#); [Somatosensory system](#)

Definition

Proprioception is considered the body’s perception and sensation of movement and awareness of tactile sensation.

Introduction

Proprioception is a general term that covers the somatosensory system. This tactile sensation is involved in the awareness of the limb per se and its movement – in other words, kinesthesia. The receptors that are in the muscles, joints, and under the skin inform the brain about the location and sensation of the specific body part. In the following headings, there will be an elaboration of what proprioception is and how it works as well as its function with rehabilitation programs and how it aids the physical recovery of an injury. Some techniques will be also introduced. Finally, there will be a very brief view of proprioception from O’Shaughnessy’s (2000) philosophical standpoint.

The Role of Proprioception

The word proprioception was first introduced by Charles Scott Sherrington in 1906 describing muscles as stretch proprioceptors (Hamant and Moulia 2016). Proprioception – often referred to as somatosensory system – is a general term that refers to a specialized component of tactile sensation that incorporates recognition of kinesthesia, i.e., the sense of joint movement, and the sense of joint position, i.e., the body’s sense of its position in terms of balance and movement (Saxby 2011; Johnsen and Agerskov 2009; Blackburn et al. 2000; Pincivero et al. 1998). It can be defined as a “special type of sensitivity that informs about the sensations of the deep organs and of the relationship between muscles and joints” (Iturri 2003, p. 274). In essence, it is the body’s awareness of the relative position of the body parts and is usually referred to as the body’s “sixth sense” (Saxby 2011; Hamant and Moulia 2016).

The proprioceptive system uses stretch and pressure receptors located in our muscles, joints, and skin, which inform the brain of the physical environment and the body’s interaction with it (Saxby 2011). Schafer (2006) described this process as a sensory feedback procedure, where mechanosensory neurons detect forces produced as an effect of the movement of the

body – such as membrane stretch – and use these data to control the activity of locomotor systems (Schafer 2006). The role of proprioceptive sensation is to receive information from the muscle-spindle receptors (see text below) and peripheral afferents such as Golgi tendon organs, the joint capsules, ligaments, and cutaneous receptors, as well as visual and vestibular receptors and convey this information to the Central Nervous System (CNS) through afferent neural pathways (Pincivero et al. 1998; Blackburn et al. 2000). Information taken from these mechanoreceptors is processed to produce a neural signal intended to facilitate neuromuscular control to compensate for any deviations in posture or gait. Joint stability and the strength of the muscles are important factors that contribute to balance (Blackburn et al. 2000).

Moreover, it has been proved that proprioception has a significant function in the skeletal muscles to regulate muscle length in response to stretch (Niechwiej-Szwedo and Steinbach 2008). These proprioceptors in the skeletal muscles are called muscle spindles and are found in the orbital layer of certain species such as humans, sheep, and some primates, but not in species such as rats, rabbits, horses, or cats (Niechwiej-Szwedo and Steinbach 2008). Muscle spindles are responsible for the sensation of position and movement, despite the fact that they are under fusimotor control as position sensors (for a review on fusimotor action see Prochazka and Hulliger 1998). An additional role of the muscle spindles is to provide peripheral feedback for the unconscious adjustments during posture and locomotion (Proske 2005). The role of tendons, ligaments, and joint capsules is not only to offer mechanical support and to induce movement but also carry mechanoreceptors which gather data on the position of the joints or the stretching of the tendons and ligaments, and send this information through the upper cord to the base of the encephalon to initiate an effective response and offer a dynamic stabilization and balanced reaction (Iturri 2003). Balance is the primary function of the vestibular system. Essentially, all these structures contain receptors that contribute to the monitoring of the body's actions through proprioception (see Proske

2005, for a review on the sense of static limb position and kinesthesia).

Besides the classical proprioceptors in the limb muscles of mammals (i.e., muscle spindles and Golgi tendon organs), it was also shown that Palisade endings are of functional proprioceptive importance. These endings are nervous end organs confined to the extraocular muscles of mammals and man and are immunoreactive for antibodies against choline acetyltransferase (Weir 2006; Blumer et al. 2006).

Regarding the case with mechanotransduction, there are still some gaps in the full understanding of the molecular and biophysical properties of these mechanoreceptors of proprioception. However, there are two ion channels families that best describe the molecular mechanisms of proprioceptor mechanotransduction. The first family is the DEG/ENaC/ASIC family of channels, which form heteromultimeric complexes with stomatins permeable to sodium and calcium. Several of these have been shown to play a significant role in mechanosensation, yet none has been reconstructed as a mechanically sensitive channel when expressed in heterologous cells (Schafer 2006). The second family is the transient receptor potential (TRP) cation channels, which are either known to play a role for in vivo mechanosensation or have been shown to be activated by mechanical forces in heterologous expression systems (Schafer 2006). Specifically, recent research suggests that TRP cation channel N1 – also known as NompC and TRP4 – are directly implicated in mechanosensation, based on a sample from fruitflies and nematode worms (Cheng et al. 2010). Cheng et al. (2010) suggested that TRPN1 plays a significant role for proprioception in *Drosophila melanogaster*. Specifically, they used a green fluorescent protein construct to show expression of the channel in subsets of peripheral sensory neurons responsible for locomotion coordination. For example, the TRPN1-null larvae crawled in less speed than the wild-type larvae, showing impaired proprioception based on the loss of TRPN1 in sensory neurons (Kingwell 2010). Additionally, TRP4 has been shown to function as an essential pore-forming subunit of a native mechanotransduction channel

(Kang et al. 2010). The authors, specifically showed that TRPN1 is responsible for the mechanoreceptor current by mutating key residues in the putative pore-forming domain of the channel protein, and they also showed that this changed the cation-selectivity of the current. Wilson and Corey (2010) further support this finding by describing the TRPN1 as the “bona fide” mechanoreceptor channel for nematode feeding behavior. It is noteworthy, however, that this specific channel (TRPN1) is not expressed in mammals, but several other TRP family members are expressed – a fact that shows promising research results in the future (Kingwell 2010).

Further research on the mechanotransduction channels of proprioception has shown that the mechanically activated nonselective cation channel Piezo2 is the major mechanotransducer of mammalian proprioceptors (Woo et al. 2015).

Proprioception and Rehabilitation

Before engaging in how proprioception can help with the coordination of muscles and rehabilitation, it is better to offer a definition of what coordination really means, as well as an explanation of relevant terms. Iturri (2003) defined coordination as “the capacity to perform movements in a smooth, precise and controlled manner” (p. 274). Therefore, in order for rehabilitation to work towards the coordination and strengthening of muscle movement, a certain re-education of neuromuscular and neuroarticular functions is needed. It is here where proprioception plays a crucial role (Iturri 2003).

In order to understand how proprioception plays this crucial role in sport, it is imperative to understand how it is different from other types of sensations. Based on Sherrington’s classification of sensitivity, proprioceptive sensation is the impressions on the functional state of the joints and muscles (Iturri 2003). These are divided in conscious proprioceptive sensation which is the awareness of passive and active movements, and the position of a somatic part of the body, in other words, kinesthesia. If the individual is not aware of these impressions, then these are called unconscious proprioceptive sensation and they relate to balance, tone, and muscular coordination (For a

full review of Sherrington’s classification see Iturri 2003, pp. 274–275). The difference between proprioceptive and exteroceptive sensation is that the latter is the sensation that is involved in the external surface, which includes touch, pressure, pain, and differences in temperatures. This type of sensation also involves other more specialized sensation such as sight, hearing, and smell. Proprioception is also different from interoceptive sensation, which is the type of sensation found in the viscera and vessels, and it can be divided in areas of gustatory and olfactory.

According to Lephart et al. (1997), rehabilitation programs should be designed to incorporate proprioception that addresses these three levels of motor control: spinal reflexes, cognitive programming, and brainstem activity. The main emphasis to this is to promote dynamic joint and functional stability not only in the rehabilitation programs but as a prevention program as well (Panics et al. 2008). Therefore there are specific ways to assess proprioception prior and post exercise or physical therapy.

Testing Proprioception at Sport

The assessment of joint proprioception is divided in two parts: kinesthesia and joint position. As Pincivero et al. (1998) suggest, kinesthesia is assessed by measuring the threshold to detect passive motion, and joint position sense is assessed by measuring the reproduction of passive positioning and the reproduction of active positioning. On the cognitive level, certain activities that require higher brain abilities are initiated; these activities could be to perform end range joint positioning activities, in order to stimulate the conversion of conscious to unconscious motor programming throughout repetitions. This conscious to unconscious transition is performed through dynamic balance rehabilitation activities by bringing awareness and concentration on the performed task in order to facilitate sensory input. The end result is to incorporate cognitive or psychomotor aspects to lead to unconscious motor programming (Pincivero et al. 1998).

Regarding the spinal level of motor control, rehabilitation activities that produce sudden changes in joint position must be included to the

unconscious processes of reflex joint stabilization. Certain activities such as training in unstable platforms and plyometric exercises enhance joint muscular contractions and reactive dynamic muscular stabilization which eventually address neuromuscular training at the spinal level of motor control (Pincivero et al. 1998).

Even by using specific psychophysical tests, the knowledge we have for proprioception is limited for the following reasons: (1) It is unknown how isolated proprioception mechanisms affect these tests; (2) it is impossible to measure proprioceptive function while the individual is under effort. Therefore, since the tests are performed while the individual is resting, the results are unreliable; (3) the results are not really understandable outside the individuals' awareness; (4) proprioceptive training has the paradoxical effect of influencing negatively the psychophysical test procedures. It has been shown, however, that electromyography can provide an orientated analysis of muscular function as the end-point of regulatory proprioceptive function (Iturri 2003).

It is noteworthy that the biggest challenge on using proprioception in sport is the lack of information about the proprioceptive situation prior to the injury. Nevertheless, it is possible to obtain epidemiological information from prior examinations based on the findings of both psychophysical and electromyographic examinations; the information gathered from minor injuries prior to a major injury that have been damaging the proprioceptive structures and directed proprioceptive training as a prognosis of injuries (Iturri 2003).

Proprioception Training Techniques

It has been demonstrated by several research studies that proprioception training reduces the injury rate in the lower extremities (Mandelbaum et al. 2005; Myklebust et al. 2003; Hewett et al. 1996; Halasi et al. 2005; Wedderkopp et al. 2003; Caraffa et al. 1996). Panics et al. (2008) have added to the existing literature that proprioception training improves the sensation of joint position in the knee joint, and that improvement in the joint position sense may be one explanation for the reduction in injury rate. It was also shown that proprioceptive training program produced

improvements in the ability to balance on a single-plane balance board and balance in general (Mattacola and Lloyd 1997; Hrysomallis 2011). Specific warm-up programs were also proven useful to increase the proprioceptive capabilities of athletes (Daneshjoo et al. 2012; Subasi et al. 2008).

Usually after an injury, kinesiotherapy and physiotherapy stimulate the exteroceptive and proprioceptive systems (Iturri 2003). Proprioceptive re-education aims to activate the muscular receptors to provide an immediate motor response (Scott and Fu 2000). Stretching, for example, has a significant proprioceptive effect on the injured area, and it gets the muscular receptors to work. Iturri (2003) suggested the following techniques for proprioceptive reprogramming: (i) balancing on unstable planes; (ii) balancing on one foot; (iii) balancing whilst sitting; (iv) sliding the foot along an unstable plane; (v) the Kabat method; (vi) semi-closed and open kinetic chain exercises. This way, individuals make integrated movements that use muscle groups that are used to work together following a set of rules: movement of the segments of the diagonal plane; a spiral component associated with each movement; and stretching stimuli which are used when applying physical resistance (Iturri 2003).

Proprioception and Consciousness

O'Shaughnessy (2000) in the last chapter of his book gives a comprehensive explanation of what proprioception is and what is not, mostly from a philosophical and psychological point of view. He specifically states that proprioception stands for:

"the familiar immediate experiential awareness of our own limbs and body... a distinctive sub-variety of perception... (proprioception) must be sharply distinguished from the attentively immediate awareness of bodily feelings like fatigue or warmth: the reason being, that these latter are mentalistically immediate perceptions of psychological objects" (p. 628).

He keeps on arguing that proprioception:

"...is an experience... whose content is caused non-deviantly by its object, and it can form the basis of an inference to the existence of that object... it is no kind of cognitive attitude, nor tendency to entertain a cognitive attitude. In short, we

have here an attentive experience in which a small sector of physical reality appears one way, which is to be sharply distinguished from cognitive attitudes of all kinds, even though it naturally sustains such” (p. 629).

O’Shaughnessy (2000) makes an interesting argument stating that in every example of tactile perception, a proprioceptive awareness of the individual’s body stands between him/her and the tactile object, and it is only if one perceives their own body he or she becomes cognizant of the objects to touch. Therefore, the sense of touch must depend upon proprioception and not the other way around. He adds that the major differences between proprioception and touch are the scope of the objects and the type of the properties, in particular the type of the spatial properties of the objects. For example, touch has no restriction in terms of surface and shape properties, whereas proprioception is limited to the sense of our limbs and body movement. In general terms, even though the sense of touch and proprioception are closely related and “body-oriented senses,” they are nevertheless not similar in a variety of levels, and neither could be reduced to the other (O’Shaughnessy 2000, p. 630).

Another curious fact O’Shaughnessy (2000) mentions in his book is what he has called “introspective proprioception,” where the limb is the focal point of attention. The difference here between introspection in general is that the attention is taken away from the outer objects and is turned inwardly towards the sensation and conscious movement of our lower and upper extremities. However, despite the fact that proprioception is needed for our normal physical interactions of the physical space around us, it stands merely by positing that it establishes no kind of distraction during any physical activity or, better yet, it stands lower in the attentional hierarchy need of a certain action.

Conclusion

In this chapter, a basic review of the role and function of proprioception was covered regarding the sensation of the physical world around us. In

essence, proprioceptive system uses stretch and pressure receptors located in our muscles, joints, and skin, which inform the brain of the physical environment and its interaction with it; a process called a sensory feedback procedure (Schafer 2006). There was also a brief overview of the specific ion channels families that best describe the molecular mechanisms of proprioceptor mechanotransduction: the DEG/ENaC/ASIC family of channels and the transient receptor potential (TRP) cation channels. Proprioception has also played a main role in the physical therapy of athletes during a rehabilitation program, as part of the re-education of neuromuscular and neuroarticular functions of the athletes and as a part of their training routine order to reduce injuries and improve balance. Lastly, as O’Shaughnessy (2000) stressed the importance of acknowledging our limbs and bodily movements as mediums of the tactile sensation we get from the physical environment, although this awareness stands true based of the level of our attention.

Prosocial Behavior

Mary Lewis
Oakland University, Rochester, MI, USA

Synonyms

Altruism; Cooperation; Donation; Helping; Sharing

Definition

Any action that benefits another organism regardless of intent or motivation.

Introduction

Prosocial behavior, as a voluntary action intended to benefit another (Eisenberg et al. 2006), is multidimensional in form, motivation, cause, and consequence (c.f. Padilla-Walker and Carlo 2014). Sharing, comforting, cooperating, helping, rescuing, and donating are among positive behaviors that benefit others. Motives may vary as a function of recipients (kin versus non-kin), contexts (relational, familial, cultural, or physical), and goals (other-oriented versus self-oriented). The term, “prosocial,” is distinguished from “altruistic” because the psychological motivation underlying their enactment differs (Carlo 2014). Whereas prosocial behavior includes both other-oriented motivations (empathic concern, internalized values) and self-oriented motivations (opportunism, reputation enhancement, good feelings about the self), altruism is exclusively motivated by other-oriented concerns and may include elements of self-sacrifice, risk-taking, or threat to the self (Batson and Shaw 1991; Carlo 2014). Scholars from an evolutionary tradition also discriminate between proximate and ultimate causes of altruism (Tinbergen 1963). Proximate causes are psychological, cognitive, physiological,

contextual, or ontological processes in the immediate environment, whereas ultimate causes address the survival function of a behavior (i.e., prosocial behavior) or its phylogenetic history. Proximate causes address *how* the behavior occurs and is the focus of many psychological theories. Ultimate causes postulate *why* the behavior evolved in the first place. Cooperation or cooperative behavior also is used as a term that falls within the dimensionality of prosocial behavior, as it is positive, coordinated behavior occurring among members of social groups to achieve a particular goal. Upon first glance, prosocial behavior seems to be a simple construct to conceptualize, yet its multidimensionality in form, motivation, consequences, and ultimate cause demonstrates its intriguing complexity.

Proximate Causes of Prosocial Behavior

Proximate causes of prosocial behaviors emphasize the psychological components of prosocial behaviors and their development. The processes involved in prosocial behavior are many and include such antecedents as genotypic predispositions, temperament, empathy and mentalizing, executive control, cognitive and social-cognitive abilities, preferences for self or other, affiliative and familial groups, and ecological niches, among many others (Carlo et al. 2016; Jensen and Silk 2014). Proximal causes also address ontogeny or the development of prosocial behavior and its correlates across the life span. Two proximal processes will be presented here, namely, the role of other-regarding preferences (consideration of the consequences of acting) and other-regarding concern (attunement to the emotions and welfare of others; Jensen and Silk 2014).

Other-Regarding Preferences: Helping and Sharing

The decision to benefit another through coordinated action or allocation of resources (e.g., food)

requires an actor to think about the consequences of their actions for others (Jensen and Silk 2014), which also requires the ability to ascertain the other's goal in order to provide assistance or share (Warneken and Melis 2012). Such preferences are considered prosocial when the choice of action enhances the welfare of another. Empirically, other-regarding preferences have been witnessed in chimpanzees using a variety of methods. Young chimpanzees were found to retrieve an object for a familiar caretaker, help a conspecific gain access to a room, and provide a needed tool to gain access to food (Warneken et al. 2007; Warneken and Tomasello 2006; Yamamoto et al. 2009). To date, chimpanzees do not give food prosocially to benefit a fellow conspecific (Jensen and Silk 2014). Using a modified prosocial game, where an actor has a choice between keeping food for the self and not giving food to a conspecific (1/0) or keeping food for the self *and* giving food with a conspecific (1/1), chimpanzees were indifferent in giving a partner food even when it did not incur any personal cost (Jensen and Silk 2014; Warneken and Melis 2012). Human toddlers do assist experimenters in a variety of ways by inferring cues from the person needing assistance and the environment (Warneken 2015; Warneken and Tomasello 2006, 2007). In contrast with chimpanzees, children share prosocially with adults and peers with increasing age as demonstrated through prosocial, dictator, and ultimatum games (Fehr et al. 2008; House et al. 2013a, b). Fairness or prosocial sharing appears to emerge in middle-childhood (ages 7–8 through puberty) when children become aware of social norms (House et al. 2013). Human children have a genuine and honest desire to help others from a very young age (Warneken 2015).

Other-Regarding Concern: The Role of Empathy

Other-regarding concern is witnessed when individuals are responsive to others' emotions and welfare motivating them to behave prosocially (Jensen and Silk 2014). Carlo et al. (2016)

distinguishes among empathy, sympathy (or empathic concern), and personal distress, as each play a different role in prosocial behavior (see also de Waal 2008; Eisenberg et al. 2006). Perspective-taking is the cognitive ability to understand the situations from another's point of view and may be implicated in particular types of prosocial behavior (Carlo 2014). Empathy, the apperception of and resonance with another's emotional state (Batson 1991; Eisenberg et al. 2006), can be positive or negative; that is, happiness is experienced when another is happy, or sadness is felt in connection with another's saddened state. Sympathy or empathic concern is felt as feelings of sorrow for another's circumstance and motivates individuals to alleviate the distress (Batson 1991). Personal distress is an overwhelming self-distress experienced by another's suffering and results in heightened physiological arousal undermining prosocial initiatives. Whereas empathy and sympathy are generally linked with prosocial behavior, personal distress is not (Eisenberg et al. 2006).

For scholars of evolutionary theory, the question is "Why has empathy evolved, and how is it linked with prosocial behavior?" According to de Waal (2008) "empathy evolved in animals as the main proximate mechanism for directed altruism. ... it causes altruism to be dispensed in accordance with predictions from kin selection and reciprocal altruism theory" (p. 282). Suggested to have evolved in parental care for their young among mammals (including humans) and birds, empathy is a selected trait because parents who were empathic and nurturing reared thriving offspring, whereas parents who were not empathically disposed left fewer descendants (Preston 2013). Evidence for the evolutionary roots of empathy comes from comparative and developmental psychology. Empathic responses to distress have been observed between and within species (Burkart et al. 2007; de Waal 2008). Ontogenetically, scholars propose the means by which empathy leads to prosocial actions among humans beginning with affective resonance followed by self-other distinction in the development of empathic concern (de Waal 2008; Jensen et al. 2014). Neonates, for example, have been shown

to affectively resonate with other infants' distress by crying themselves, suggesting an innate tendency to emotionally connect with others. Self-other distinction emerges around 18 months of age and allows toddlers to mentalize about the plight of the other within the situational parameters (de Waal 2008; Jensen et al. 2014). Once children experience empathic concern, understands others' point of view, and care about another's welfare (positive-other regard), then they are likely to act prosocially (de Waal 2008; Jensen et al. 2014). Recent evidence suggests that cultural or social context interacts with children's empathy and other-regarding tendencies to determine in what ways and how often they might intervene (Jensen et al. 2014). In other developmental research, temperament, defined as biologically based "individual differences in reactivity and regulation" (Rothbart et al. 2000), also is linked to more or less frequent prosocial activity (Carlo et al. 2016). Fear-proneness, negative emotionality, and executive control, in particular, may modulate the degree to which empathy might prompt prosocial behavior (Carlo et al. 2016). In sum, affective resonance or attunement appears to be shared across many species, but the capability of acting on empathy is a uniquely human quality (Tomasello 2014).

Ultimate Causes of Prosocial Behavior

Ultimate causes of prosocial behavior would identify the means by which lifetime fitness benefits are accrued and gene transmission is preserved through reproductive success. However, altruism is an act or set of actions that bestows a fitness benefit to another at an apparent cost to the actor. Several theories have worked to explain the presence of altruism in human evolution. Among those seminal ideas are (a) kin selection (Hamilton 1964), (b) reciprocal altruism (Trivers 1971), and (c) indirect reciprocity (Alexander 1987).

In the theory of kin selection, Hamilton (1964) demonstrated that altruistic behavior would be selected as a trait if the fitness costs to the benefactor were less than their recipients'

benefits multiplied by their degree of kinship ($[C < rB]$, where C = cost, r = relatedness, and B = benefit). That is, he measured "inclusive fitness" or the degree to which genetic material is shared with descendant kin versus non-descendent kin to determine the likelihood of acting altruistically toward another. From a genetic fitness standpoint, the more the benefactor and beneficiary are genetically related, the less costly the act becomes.

Empirical evidence for Hamilton's premise is abundant (Bourke 2014). Humans and members of many social species will behave altruistically for the sake of preserving their kin and genetic heritage (Hames 2016; Silk 2009). Cooperative and altruistic behavior has been explained through kin selection in amoeba, eusocial insects, and vertebrates (Mehdibadi et al. 2006; Russell et al. 2003). Empirically, kin selection explains the presence of cooperative courtship in *leks* (small groups of avian males that aggregate for the sole purpose of attracting females for mating) and helping networks among several species of birds (McDonald et al. 2016). Altruism among primates (e.g., in the form of grooming, food sharing, and alloparental care) consistently show favoritism toward close maternal kin (Silk 2009). Among humans, family members are more likely to foster kin than non-kin and do so in a way that is more beneficial to the children's growth and development; kin also are more likely to help fellow kin in high-risk or high-cost situations (c.f. Hames 2016). Yet, despite the wealth of evidence enjoyed for over four decades (see Hames 2016), kin selection theory is not without its critics (Nowak et al. 2010). The heart of criticism focuses on the puzzle of why individuals would behave altruistically or cooperatively toward non-kin when there appears to be no direct fitness benefit.

Reciprocal altruism complements kin selection to account for the presence of cooperative or altruistic behavior among unrelated individuals (Trivers 1971). Trivers (1971) proposed the notion of reciprocal exchange between conspecifics and cross-species cooperators. Often called "direct reciprocity," this form of altruism relies on the expectation that assistance bestowed will be assistance received in the long term. Thus, an

altruistic action would *not* ultimately be costly and, in fact, would be driven by genetic self-interest. The tit-for-tat exchange exemplified in the prisoner's dilemma demonstrated that direct reciprocity worked well as long as there were adequate numbers of members to ensure the cooperative strategies. Furthermore, when pitted against other social strategies in game theories, direct reciprocity gave way to more kind exchanges (forgiveness, in essence) during which periodic lapses are overlooked for longer term gain (win-stay; lose-switch approaches). Direct reciprocity has been observed primarily among humans and chimpanzees (Schnino and Aureli 2007) but rarely in other species (Clutton-Brock 2009).

Indirect reciprocity is another theory that addresses the presence of altruistic and cooperative behavior among non-kin (Alexander 1987). The basic premise of indirect reciprocity is the notion that individuals exist among a community of exchange partners, such that those who are observed to help others are the most likely to receive help themselves (Nowak and Sigmund 2005). A good reputation leads to direct fitness by receiving material resources long term as well as to genetic fitness through choice of potential mates. Those who are "freeloaders," that is, those who do not contribute their share, might gain in the immediate but lose in the long term by being ostracized, punished, or afforded diminished reproductive opportunities. Being able to distinguish between cooperators and freeloaders becomes a necessary and selective skill. The "partner choice" models in which cooperative partners are chosen over those who cheat are witnessed in cross-species and within-species partnerships (Baumard et al. 2013). Young children also selectively help others, provide resources, and give information to those who they witnessed acting prosocially toward others (Kuhlmeier et al. 2014). Even infants preferred *helpers* to *hinderers* in a series of experimental studies examining the early presence of social judgments (see Wynn and Bloom 2014 for a review). In sum, selecting those who act prosocially toward others not only aids the individual but benefits the survival fitness of a social group.

Conclusion

Prosocial behavior has multiple expressions and is multiply determined. Although rudimentary aspects appear in primates, many components seem to be uniquely evolved human capacities (Tomasello 2014). Innate tendencies, such as other-regarding preferences and concerns, are found in studies of early human ontogeny. Children demonstrate a genuine desire to help others, a sense of prosocial fairness through sharing, and an emotional sensitivity to promote another's welfare. Over time, these basic acts of kindness, generosity, and helpfulness led to coordinated and collaborative efforts that promoted interdependence and ultra-sociability (Tomasello 2014).

Definition

Prosopagnosia is characterized by impairment or inability in recognizing or distinguishing human faces.

Introduction

Prosopagnosia is a condition that inhibits the ability of individuals to recognize, remember, or distinguish human faces. Although this deficit can cause social distress, other sensory and cognitive functions are often unimpaired. Recognizing individuals is a crucial ability in social species, and face identification is the primary form of person recognition in humans. Face-specific areas of processing have also been identified in the brains of macaque monkeys (Tsao et al. 2006), suggesting that face recognition has been a persistent component of much of human evolutionary history. Because human facial recognition continues to be a ubiquitous feature of human social interactions, many prosopagnosics rely on other characteristics such as hairstyle or voice audio signatures to identify individuals and conduct social interactions.

Prosopagnosia and Modularity of the Mind

The term *prosopagnosia* was first used by Bodamer (1947) to describe a patient who exhibited difficulties in recognizing faces after suffering a head injury. Prosopagnosia can be acquired following a traumatic injury to the brain as in Bodamer's case but can also occur naturally. Prevalence for congenital (or developmental) prosopagnosia is estimated to be as high as 2.5% (Grüter et al. 2008) and has been observed to cluster in families, suggesting possible genetic contributions. Congenital prosopagnosia is also much more common than acquired prosopagnosia. Onset of prosopagnosia has been associated with abnormalities or damage of the fusiform gyri (e.g., Gainotti and Mara 2011), in particular the anterior fusiform gyrus

(Behrmann et al. 2007). In addition, bilateral gray matter loss has been noted in the temporal lobes of prosopagnosics, with greatest loss being in the right temporal lobe, particularly in the amygdala, hippocampus, parahippocampal gyrus, fusiform gyrus, and anterior temporal pole (Josephs et al. 2008). Prosopagnosia has been found to have a high comorbidity with cerebral achromatopsia (i.e., impairment of color vision acquired by trauma to the cerebral cortex; Bouvier and Engel 2006) and can co-occur with other identification impairments, such as semantic dementia (i.e., deficits in recognizing and naming objects; Josephs et al. 2008). Some brain injuries, such as right anterior temporal lesions, may produce inability to recognize faces, but are often not limited only to failures in facial identification, and are better understood as “multimodal people recognition disorders” (Gainotti and Marra 2011).

Disorders such as prosopagnosia and achromatopsia have been used to support the modularity of the visual perception system, as certain aspects of a sensory system may be dysfunctional (e.g., face perception), while other perceptual aspects remain intact (Celesia 2010). This modularity manifests in fairly independent functioning, such that various perceptual components of a perceptual system can function or falter relatively autonomously leaving other components relatively unaltered. For instance, prosopagnosics often have limited interruptions in other visual perceptions such as luminance discrimination, spatial resolution, and line and curvature orientation (Barton et al. 2004). Modularity of the visual field mirrors the proposed modularity of other perceptual systems in the brain and the mind in general (e.g., Cosmides and Tooby 1994). This modularity suggests that perceptual systems evolved rather independently to convey context specific advantages to ancestral humans and that even component parts retained a high degree of functional and structural integrity after integration into the perceptual systems of contemporary humans. This independence can also be observed in cognitive modules that rely on a shared perceptual system for information. For instance, the person-identity-recognition system and the emotion-recognition system of the brain are both

heavily reliant on visual input. However, they appear to be independent systems such that prosopagnosics have been shown to maintain the ability to distinguish and identify facial cues related to emotional states (Duchaine et al. 2003). This ability to recognize facial cues to emotion sans person-identification indicates that these seemingly related modules, both pertaining to recognizing facial cues, are differentially distributed in the neural cortex.

Deficits in recognizing spatial relations and contrast sensitivity have been proposed as the central apperceptive components of prosopagnosics' inability to distinguish faces, especially in acquired prosopagnosia (Barton et al. 2004). There have also been differences shown in the ability to perceive static versus dynamic faces (Steede et al. 2007), suggesting the importance of facial movements in conveying information and perceiving mental states. This finding also suggests that the difficulties in facial recognition stem more from recognizing idiosyncratic morphology rather than movement. Treatments for prosopagnosia tend to focus on developing and fostering these same compensatory strategies, such as recognizing other individual differences besides facial structure. Most success in treatment has come from improving the ability to attend to other distinguishing features such as voice pitch, clothing, hair style, and gait. Such treatment has been suggested for both congenital and acquired prosopagnosia (Cousins 2013).

Conclusion

Facial apperception can be a major impediment to intraspecies interactions, but prosopagnosics can still become adept at navigating social interactions without the use of facial recognition by relying on other identifying cues such as voice, clothing, and gait to discern the identity of individuals. Although prosopagnosia may be comorbid with other perceptual disorders such as achromatopsia and semantic dementia, it often does not inhibit most sensory functions. Impairment of one function of a perceptual system with maintenance of other functions in the same system, as is seen in

fairly stable performance of prosopagnosics in emotion recognition and curvature discrimination tasks, may suggest the independent evolution of functions of a particular perceptual system to solve particular ancestral problems. Thus, this divergent functioning fits with the modularity model of the evolved modern human mind.

Prosopagnosia (Face Recognition)

Alfredo Ardila

Sechenov University, Moscow, Russia

Albizu University, Miami, FL, USA

Florida International University, Miami, FL, USA

Synonyms

[Face blindness](#); [Visual agnosia for faces](#)

Definition

Prosopagnosia is a subtype of visual agnosia characterized by an impairment in the ability to recognize familiar faces, including one's own face.

Introduction

The word prosopagnosia comes from the Greek *prosopos* (face or person) and *gnosis* (knowledge). Although acquired disorders in face recognition have been described since the nineteenth century, Bodamer (1947) was the first researcher to use the term “prosopagnosia” to define the disorder in face recognition, isolated from other types of visual agnosia.

Clinical Characteristics

The patient who suffers from prosopagnosia loses the ability to recognize people by the face and has to resort to the recognition of accessory aspects to the face such as voice or clothing to achieve identification. It is a selective deficit of facial

identity, frequently (but not always) retaining the ability to interpret other types of facial information, such as emotional expression, age, and sex. In very serious cases, the patient loses the ability to determine the sex and age of the face (Lopera and Ardila 1992).

Patients with prosopagnosia recognize the differences between faces and are able to match similar faces, but cannot achieve their identity. Sometimes, the defect can extend to the patient's own face with impossible recognition in a mirror or a photograph, and the patient even indicates that he/she has forgotten what his/her face was like. The patient can, however, know that a face is a face and that it contains certain elements, such as eyes, nose, etc.

Prosopagnosia then seems to be a defect in recognizing individual members belonging to a specific visual category, and most patients also have difficulty recognizing the individual members of stimulus groups that belong to other visual categories (e.g., cars, flowers, animals, etc.). The patient can recognize the category ("it is a car") but be unable to determine what type of car it is, that is, the individual member of the category. So, in prosopagnosia, the recognition of the specific members belonging to a visual class is altered, despite the recognition of the class being achieved.

It has been observed, however, the presence of a covert recognition of faces in patients with prosopagnosia. Patients present a physiological response to familiar faces but not to the presentation of unfamiliar faces (Sergent and Poncet 1990). Likewise, better learning is achieved in tasks of associated pairs of faces if family faces are used for the patient. These findings suggest that despite not being aware of face recognition, the patient is performing a partial covert recognition, of which he/she is not aware.

Prosopagnosia is a relatively unusual neuropsychological syndrome and its anatomical correlates are still under discussion. From the initial descriptions it was considered that lesions of the right hemisphere were sufficient to produce prosopagnosia. This theory was maintained until 1980 when some pathological studies (Damasio et al. 1982) showed the presence of bilateral lesions in patients with prosopagnosia and described the temporal inferior and basal occipital

regions (fusiform and lingual gyri) as the determinants in the production of the syndrome, with all its clinical manifestations. Since 1985, however, new radiological studies have appeared with injuries exclusively in the right hemisphere (Vg., Landis et al. 1988) centering the anatomical location of prosopagnosia again toward the right hemisphere. The damage of the inferior temporal-occipital portion of the right hemisphere seems to be crucial but not sufficient in the production of prosopagnosia. Benton (1990) suggests that the production of prosopagnosia can be observed in cases of an exclusively right lesion, provided that it is associated with some abnormal condition of the left hemisphere, such as an atrophy associated with aging. De Renzi (1982) proposes that the production of prosopagnosia due to lesion of the right hemisphere depends on the size of the lesion. The lesion must reach a certain size that allows the appearance of the syndrome, but neither should it be very extensive since wider agnostic phenomena would opaque the defect in the recognition of faces.

More recently, it has been observed that prosopagnosia can appear as developmental disorders, usually referred as "developmental prosopagnosia." Developmental prosopagnosia can be defined as a severe impairment of visual face recognition in the absence of any apparent brain damage (Towler and Eimer 2012). These patients with developmental prosopagnosia usually report first experiencing face recognition problems in childhood or adolescence. Typical diagnostic criteria are that developmental prosopagnosia individuals must score below two standard deviations from the mean on a number of different face recognition tests (Towler et al. 2017). Developmental prosopagnosia has attracted special attention during recent years, and a significant number of papers exploring this developmental disorder have been published (Pennington et al. 2019).

Conclusion

Prosopagnosia represents a relatively unusual clinical syndrome observed in cases of the temporal inferior and basal occipital pathology. It is

characterized by inability to recognize familiar faces and, frequently, to recognize the individual member of a visual perceptual category. Some disagreement remains regarding the lateralization: where some authors state that right hemisphere lesions are sufficient to produce this syndrome, other authors consider that a bilateral pathology is required. Recently, it has been reported that face recognition difficulties can also appear as a developmental specific learning difficulty. The name of “developmental prosopagnosia” has been used to refer to this developmental abnormal condition.

Prospective Mates

Christopher J. Holden

Department of Psychology, Western Carolina University, Cullowhee, NC, USA

Synonyms

[Potential Mates](#)

Definition

Of all available mates, prospective mates are those that the individual has selected for further pursuit and may be investing time and resources in these individuals in an attempt to secure them as a long-term mate.

Introduction

As one of the most widely studied areas in psychology, self-esteem has been demonstrated to influence a number of outcomes. Most typically, differences emerge for individuals with high self-esteem and those with low self-esteem. The processes surrounding the selection of mates are no exception to this pattern of results. That is, individuals high in self-esteem score higher on self-reported attractiveness (Bale and Archer 2013). Additionally, it has been demonstrated that feedback from potential mates influences state self-esteem (i.e., feelings of self-worth in the moment; Kavanagh et al. 2010).

Self-Esteem and the Selection of Mates

As a species, we are motivated to seek high-quality mates, which in turn increase our reproductive success. There are a number of physical markers of attractiveness, as well as personality traits, such as self-esteem, that influence attractiveness. More specifically, it has been demonstrated that individuals with high self-esteem

report higher ratings of their own attractiveness (Bale and Archer 2013). Considering these findings in terms of sociometer theory, Leary et al. (1995) help to elucidate the nature of this relationship.

Sociometer theory (Leary et al. 1995) suggests that self-esteem acts as a status-tracking mechanism. That is, self-esteem functions to give us information about how valued we are by others. Therefore, individuals who are valued by others should have high levels of self-esteem (Leary et al. 1995). Understanding the degree to which we are valued and included by others would have had tremendous survival and reproductive benefit. Thus, it has been proposed that a “mating sociometer” exists, such that individuals are sensitive to how valued they are by potential mates (Kavanagh et al. 2010).

Multiple studies provide evidence for the mating sociometer. More specifically, it has been demonstrated that experiencing rejection from a potential mate significantly lowers state self-esteem (Kavanagh et al. 2010; Pass et al. 2010). Furthermore, this decrease in self-esteem influences mating aspirations (Kavanagh et al. 2010). That is, individuals who receive a rejection from a potential mate report a decrease in self-esteem and tend to pursue mates of lower attractiveness, while avoiding mates high in attractiveness (Kavanagh et al. 2010). Additional studies have demonstrated that this decrease in self-esteem following rejection is coupled by a decrease in self-perceived mate value (Zhang et al. 2015). Furthermore, individuals who experienced rejection reported a desire to evade situations wherein potential mates may be present, whereas individuals who experienced acceptance did not (Zhang et al. 2015). Therefore, decreased self-esteem may continue to influence mating decisions, as well as accessibility to quality mates.

Interestingly, this connection between rejection and decreased self-esteem is not observed in other domains, such as friendships, where individuals may face rejection (Kavanagh et al. 2010; Pass et al. 2010). Therefore, the sociometer may be particularly tuned to the domain of mating. This is further evidenced by research suggesting that self-perceived attractiveness, self-confidence

in appearance, and romantic self-confidence predict overall self-esteem (Bale and Archer 2013). These findings suggest that a large portion of self-esteem may be derived from the ability to attract a mate, which in turn suggests that self-esteem has an adaptive function for mating. If this is the case, it would then be expected that the cues to attractiveness for men and women would be different (i.e., status vs. physical attractiveness), and thus specific forms of rejection may be more impactful for men than women and vice versa. Indeed, it has been demonstrated that decreased state self-esteem in men only occurs after rejection stemming from their competence and status, whereas women only experienced decreased state self-esteem when the rejection was focused on their physical attractiveness (Pass et al. 2010). Therefore, the sociometer can be seen as particularly tuned to the domain of mating, but slightly differently tuned for men and women. Additionally, the findings discussed above suggest that individuals with low self-esteem are likely to be mated to individuals with similarly low levels of self-esteem, whereas individuals with high self-esteem seek out other high self-esteem individuals.

Narcissism and Prospective Mates

Thus far, it has been suggested that high self-esteem may reflect generally positive appraisals of one's attractiveness (i.e., from the self and from others), which in turn influences reproductive success. Therefore, it may be assumed that individuals who have particularly high self-esteem (i.e., narcissism) are more successful with prospective mates. However, this relationship may not be as clear-cut as assumed.

In many conceptualizations, narcissism is characterized by inflated feelings of self-worth (i.e., high self-esteem; Campbell and Foster 2007). As was previously discussed, individuals with high self-esteem have been deemed to be more attractive. It therefore stands to reason that narcissistic individuals would also be deemed more attractive. Indeed, it has been demonstrated that narcissistic individuals are reported to be more attractive (Dufner et al. 2013). However, this initial

attraction eventually fades, as partners of narcissists report lower relationship satisfaction, and these relationships are typically short-lived (Brunell and Campbell 2011). Additionally, narcissists have been found to be less committed to their ongoing romantic relationships (Campbell and Foster 2002) and more likely to be aggressive toward their partners (Keller et al. 2014). Therefore, narcissism may be somewhat beneficial in the initial selection of mates, and in short-term mating, but could be detrimental for long-term mating.

Conclusion

Self-esteem can be seen as a trait that influences attractiveness, and in turn the selection of mates. Typically, individuals who are high in self-esteem are deemed to be attractive and are motivated to seek out other attractive high-quality mates, whereas individuals with low self-esteem may avoid seeking out these mates. Put another way, self-esteem may be one of the many traits that play a role in assortative mating. Finally, although excessively high self-esteem may aide in early selection of mates, it appears to be detrimental to long-term mating efforts.

Definition

A sexual activity provided by women, men, and transsexuals in exchange for payment.

Introduction

Prostitution is sometimes called the “world’s oldest profession” and has been practiced throughout ancient and modern culture. The beginnings of this profession date back to ancient Mesopotamian civilization and expanded to ancient Greece, Rome, Japan, and China (Sanger 2015).

History of Prostitution

In antiquity, prostitution was connected with a secular rite (Sanger 2015). In the temple of the goddess of love, priestesses in exchange for donations for the goddess would offer up their bodies (Doufor 1902). Once a year in the Mylitty temple in ancient Babylon, each woman had to give herself to a foreigner, who would pay, in order to fulfill their sacred duty (Doufor 1902). In ancient Greece, the first brothels (*lupanarium*) were created in Athens by Solon in the sixth century BC. Prostitution was public and legal in ancient Rome (Sanger 2015). A special office was established in 260 BC, which was coordinated by an aedile. Aediles were responsible for guarding the peace in the *lupanarium* and controlling the taxes of income from prostitutes (Sanger 2015). Prostitution life was a concern in many public places. In the Roman baths, for example, special cabins existed, where erotic massages and oral and classic sex were performed by both female and male prostitutes (Sanger 2015). Prostitution practices from ancient Rome were uncovered on a fresco from Pompeii. Prostitution was common in many large cities during the Middle Ages. Professional prostitutes wore red bows on their arms as a sign of pride of guild membership, with the income from brothels feeding the municipal treasury. In the Middle Ages, the first similarity to red light districts was established, with the names of the streets referred to erotic or sex services (e.g., *Pousse-Penil* or *Puits d’amour*). Attitudes began to harden against prostitution in the sixteenth century. Syphilis transmitted to Europe from Columbian expeditions to America could have contributed to this (Harper et al. 2008). Practicing this profession became a crime, a transgression against human and divine laws. Together with this new type of crime, new ways of administering the penalty were created. Published by Charles V in 1530, *Norms and the Police Reform* severely prohibited prostitution with the penalties contained in them being extremely cruel. The eighteenth century was “The Golden Age of Prostitution,” and during this period, prostitution was widely popular. There were numerous places in Paris and London where prostitutes could receive

training in order to be professional and adaptable (Roberts 1992). Prostitution began to develop in the USA at the beginning of the nineteenth century, where bawdy houses were tolerated in American cities (D'Emilio and Freedman 1988). New Orleans is viewed by historians as the largest city brothel of all time. Various systems of regulating prostitutes and monitoring brothels were developed in Europe (Head 2009). Many prostitutes sexually served soldiers of both sides during World War I and World War II. Many soldiers were exposed to venereal diseases through these interpersonal contacts. In the Japanese war brothels, 200,000 women from China and Korea, called "comfort women," were forced into prostitution (Head 2009). Sex tourism, defined as travelling for sexual intercourse, emerged as a controversial aspect of Western tourism and globalization in the late twentieth century.

Regulation and Control

Prostitution functioned on the borderline of legality for centuries. The dynamic development of various erotic sectors was conducive to prostitution. Prostitution and the use of its services were socially stigmatized. Lack of control in many countries led to a different pathology, emerging as a profession whose cultivation was exposed to condemnation, violence, illness, and a breakdown of personal life. The prospect of quick earnings attracted women from different backgrounds, initially achieving success and then realizing the competition.

Prostitution is prohibited in 4 European Union countries, illegal in 16, and legal in 7 (Danna 2014). In the Netherlands, prostitution is legal and the most popular, especially in Amsterdam. Sex workers in the Netherlands, like in most European countries, were illegal prior to 1911 and considered criminals. New Dutch laws, however, legalized brothels, and sex workers began to be seen as any other business (Kilvington et al. 2001). Sex workers in the Netherlands have gained full social, legal, and employment rights but lost their anonymity (Kilvington et al. 2001).

Regulation and control of this profession could significantly contribute to reduction of the frequency of sexually transmitted diseases, reduce

crime on prostitutes and their clients, and eliminate prereproductive prostitution.

Service and Deviation

Individuals who work in the field of prostitution are called "sex workers." The term "sex workers" includes prostitutes who are streetwalkers, who work independently with clients, work through agencies, or who work in sex clubs or massage parlors (Clements 1996; DeCou 1998). Offering sex over special websites is particularly popular in the sex business (e.g., Prokop et al. 2018). Approximately 90 percent of sex workers are female, 10 percent male, and less than 1 percent transsexual (McGuire and Gruter 2003). The majority of prostitutes are of a reproductive age, ranging from 20 to 25 years old, which usually have the highest price per hour (Sohn 2016a; Prokop et al. 2018). A worrying phenomenon is present-day prereproductive prostitution (age 6–15), particularly in Asia. Berkman (1996) estimated that approximately a million child prostitutes are abused in India, Thailand, Vietnam, Sri Lanka, and the Philippines.

Sex workers provide not only classic sex but also sex massages and/or oral stimulation (sometimes for an additional fee). Moreover, different sexual deviations are also catered to anal penetration (client or prostitute), rimming, fisting, watersports, scat, sadomasochism (e.g., BDSM, sadistic personality disorder), and gangbangs (Pitts et al. 2004; Adriaenssens and Hendrickx 2012).

Customer Preferences

Males generally prefer younger and attractive females (Buss and Schmitt 1993). An individual who employs a prostitute's services uses the short-term pleasure without long-term effort. Additionally, engaging the services of a prostitute fulfills sexual desires not supported by regular partners (Pitts et al. 2004). Sohn (2016a) has demonstrated the price of sex with a prostitute as a good measurement of revealed male preferences. Sohn's (2016a) study, based on 8560 prostitutes from Indonesia, found that the price of sex decreased with the prostitute's age. The same results were found by Prokop et al. (2018) based on 2379

Polish prostitutes, where age and the body mass index negatively correlated with the price of sex. However, breast size (except for very large breasts) and the number of sexual offerings were positively associated with the price for sex (Prokop et al. 2018). Clients' preferences play an important role in unsafe sex with prostitutes, contributing to the transfer of venereal diseases (Adriaenssens and Hendrickx 2012). The first reason for unprotected sex is motivation for the additional price for sex without condom use (Adriaenssens and Hendrickx 2012). The second reason may be inspired for fear of violent reactions by clients (Willman 2008; Shannon et al. 2009). These two possibilities are, of course, not mutually exclusive.

Male Prostitution

Male prostitution has been found in almost all modern and ancient cultures (Dynes 1990) but has been studied far less by researchers. Male sex workers sell sexual services for women or men. Apart from money, heterosexual male prostitutes seek out sexual benefits and novel sexual practices. Females who make use of male prostitution often do not have time to get involved in relationships or have certain sexual requirements.

An Evolutionary Perspective

There is no evidence that prostitution has influenced the evolution of any aspects of human behavior, but we can use an evolutionary perspective to explain female engagement in prostitution and male (but not female) investment and cues of male preferences for female prostitutes. First, the parental investment theory suggests that females are reproductively more limited in terms of sex, and thus, females are choosier about sex than males and invest less in intrasexual competition (Trivers 1972). Indeed, females engage in prostitution more than males, and about 69% of American males have solicited a prostitute. In contrast, less than 1% of females solicited a male prostitute (Kinsey et al. 1948). This suggests that females can utilize male material investment as exchange for sexual intercourse. Secondly, the sexual selection theory (Darwin 1871) suggests that intersexual attractiveness is associated with preferences of

fertility and/or good genes. Male preferences for young females with low BMI and medium sized breasts, typical cues of female fertility (Jasienska et al. 2004), strongly support the idea that female prostitutes exploit men's ancestral preferences for fertile females. Females may further exploit men's preferences by means of plastic surgery, specific clothing, etc. Finally, the sperm competition theory (Parker 1970) posits that sperm from two or more males can compete for fertilization in the female reproductive tract. Males prefer cues of low sperm competition intensity (Prokop 2015), which ultimately increase paternity certainty. Young and less experienced female prostitutes are more attractive to males (Sohn 2016b), and popular media often provide information that young females can sometimes sell their virginity for hundreds of thousands of dollars. According to some evolutionists, sexually transmitted infections causing infertility and, in turn, divorcees can contribute to the prevalence of prostitution (Rózsa 2000; Apari et al. 2014).

Conclusion

All this information supports the idea that male preference for female prostitutes is a short-term mating strategy, ultimately influenced by the high probability of conception. These ancestral preferences still persist despite the frequent use of contraception in the modern world.

Prostitution and Legal Regulation of Sex

Leonardo C. Holanda and Mariana Gonçalves Farias
Federal University of Ceará, Fortaleza, CE, Brazil

Synonyms

Sex trade; Sex work

Definition

The act or practice of engaging in sexual activity for economic or resources profit.

Introduction

Prostitution occurs in several countries, such as US, Japan, Poland, Germany, Ethiopia, among many others (Buss 2003). McGuire and Gruter (2003), from the analysis of the number of sex workers in the USA and in some countries of

Asian, estimate an increase in prostitution around the world, mainly child prostitution. Although there are other types of prostitution such as child, transgendered and male prostitutes, in general, it is a service exercised by women (Salmon 2008).

It is commonly known that prostitution involves payment for sex. However, others services may be offered, according to customer demand. Indeed, McGuire and Gruter (2003) affirm that over 50% of call girls attendances do not include sexual intercourse. Although prostitution includes a range of different services, such as escort and indoor attendance, the most known form of prostitution is street work. Therefore, these services have a variety of benefits and disadvantages. It is a fact that street work is the most dangerous and the worst paid compared to others forms of sex work. These women have very often lower socioeconomic conditions and suffer more attempts of physical and sexual violence at work. In turn, escorts and indoors forms a high class of prostitutes. They commonly come from a healthier family environment and are well paid (Salmon 2008).

Prostitution is considered a reflection of men's preference for casual sex and a women's choice or need to offer sex in exchange of money; hence it can be motivated by the lack of resources (Buss 2003). Although there have been reports of cases in which prostitution was carried out voluntarily, the reasons and motivations of these individuals are still poorly understood (McGuire and Gruter 2003).

Prostitution and Evolution

It is possible that an exchange of sex for resources and protection occurred between hominids since early societies and prostitution as we know it today may have derived from this behavior (Salmon 2008). Prostitution can also be understood as a product of within-species variance or evolutionary variance (Buss 2003). This process is responsible for many advantageous features and mechanisms; nonetheless, it can sometimes produce and select not so beneficial features to the

human species, such as the desire to engage in law-breaking behavior or some personal and sexual preferences related to prostitution.

Engaging in sexual intercourse with prostitutes offers for men the advantages of short-term relationship without the efforts of a long-term mating (McGuire and Gruter 2003). Evolutionarily, men are more oriented to seek short-term sexual relationships, since they pursue the largest number of partners possible and are the less-investing sex, in view of the low effort after copulation and during pregnancy. In other words, since they are imposed low obligatory parental investment, men tend to be more receptive to brief sexual encounters (Schmitt et al. 2001). Moreover, prostitutes represent an alternative to individuals that had not found or could not attract a mate or were not sexually satisfied in their relationship (McGuire and Gruter 2003). Thus, in several cases, prostitutes can fulfill the sexual satisfaction of these individuals.

Another point of view is that some women use prostitution consciously as a means to take advantage of men's sexual desire in exchange of resources. Female reproductive success is more linked to the quality of partners than quantity. Instead, short-term mating represents to women a chance to access high-quality genes, protection, or immediate resources (Schmitt et al. 2001).

Legal Regulation of Sex

Being a wide spread behavior and a way of living, for many women it has been tried, for many years, to eradicate or control prostitution. Even though the reasons for the regulation of prostitution often revolves around moral and religion matters, such as threatening marital institution and family, this practice also have imposed negative social consequences, such as facilitating the spread of sexually transmitted diseases (McGuire and Gruter 2003).

As a solution for this issue, three measures have been proposed, namely, criminalization, decriminalization, and legalization (Lutnick and Cohan 2009). Making prostitution a crime could be justified based on the presumption that the act of paying for sex would be suppressed if legal

consequences were imposed for those who practice it. In the other hand, decriminalization seeks to avoid the byproducts of coercive control of prostitution, which is the increase of criminal behavior or and prostitution itself (McGuire and Gruter 2003). Cunningham and Shah (2014) state that decriminalization in Rhode Island District in 2003 considerably reduced forcible rape offenses and gonorrhea occurrence in the region. Nonetheless, this measure does not insure, in every case, that the health risk commonly associated with prostitution is controlled.

That is the main goal of legalization. Registering, licensing, and checking up for health problems regularly would help in the control, mainly, of sexually transmitted diseases (Quast and Gonzalez 2016). However, this proposition falls short in the way that it does not contribute to other matters related to prostitution other than controlling for diseases, such as the risk of violence involved in the activity, which could lead to long-term physical and psychological complications.

In this sense, none of these public policies and regulations had been fully effective. Most legal approaches involve the control of streetworking, but services like social companionship performed by call girls and escorts are more difficult to control.

Conclusion

Prostitution is widely practiced, historically persistent, and resistant to control policies activity. Despite the moral judgment implied for those who sell sex for a living, this behavior have its roots founded in human evolutionary history. The way men tend to engage in short-term sexual activity have been selected throughout the ages and has probably contributed to the survival of our specie, as well the possibility of women benefiting from it (Buss 2003). It is also important to emphasize that, from the evolutionary perspective, sexual activity and resource acquisition and maintenance are key to motivate behavior and considering that prostitution, by definition, involves both of these elements, is

safe to say that this conduct will be still practiced for many years to come.

For that reason, it is possible that any attempts to regulate sexual behavior, including prostitution, will only bring partial and temporary results, insofar human species is predisposed to engage in sexual behavior (McGuire and Gruter 2003). Thus, Salmon (2008) states that any public policies on prostitution, to be truly effective, needs to be grounded on the knowledge of evolved specialized psychological mechanisms and environmental influences related to sexual behavior.

Prostitution and Women's Short-Term Mating

Michael J. Dunn

Cardiff Metropolitan University, Cardiff, UK

Synonyms

Escorting; Harlotry; Sex-work; Whoredom

Definition

The practice or occupation of engaging in sexual activity with someone for payment.

Introduction

Symons (1979) once said that “sex is something that women have, and men want.” It is a universal truism that men in every known culture and epoch are the sex that almost invariably pay for sex, with women offering this commodity as a service for cash or other resources (Salmon 2008). The opportunities that arise for women to engage in professions where sexual services are exchanged for money or resources reveal much about both men's cross-cultural and historical desire for sexual variety and women's decision to select men to mate with who possess wealth and a willingness to exchange this for sex (Monto 2000). Clearly there are circumstances where women are indeed coerced into prostitution; however, men do not, and never have, visited prostitutes under coercion, and women appear to be well aware of men's inclination to pay for sex. Offering sex for immediate resources may indeed be a short-term strategy that women strategically employ in specific, evolutionarily relevant contexts.

What's in it for the Woman?

Women engage in and enjoy uncommitted sex for a variety of nonfinancial reasons (Meston and

Buss 2009); however whereas male fitness can be enhanced by accessing multiple partners even in rapid succession (e.g., the Coolidge effect), with negligible costs, the same fitness benefits do not, at least superficially, accrue to females who seek sexual variety. With this in mind, why have so many women across historical time and cross-culturally offered sex for money? The frequent explanation as to why women offer sex for money (i.e., to address dire economic circumstances) is challenged in that many women choose to engage in this activity despite possessing financial stability and freedom (for a summary on the historical and demographic statistics pertaining to prostitution, see Salmon 2008). It is pointless denying the incontrovertible fact that many women engage in prostitution due to male coercion especially in certain sociocultural, demographic, and economic circumstances; however, in the absence of exploitation, what reasons do women give for becoming prostitutes? Rossler et al. (2010) asked a large sample of European and non-European prostitutes in Switzerland (where sex work is not illegal) to list the reasons they chose sex work as a profession. Those coerced into the profession and those citing drug addiction comprised only 2% and 22%, respectively. Even paying debts (24%), supporting family (26%) and being unable to find another job (29%) were considerably less than the percentage claiming that the reason for their involvement in prostitution was that they “liked the job” (37%). The universal existence of prostitution in the absence of a necessity to escape poverty suggests a more deep-rooted context triggering, strategic behavioral proclivity. How can women benefit from pursuing behavior when the associated costs would appear to outweigh any benefits, e.g., promiscuous reputation, rearing offspring in isolation, absence of partner protection, and increased likelihood of contracting sexually transmitted diseases?

Greiling and Buss (2000) listed five classes of benefits that may accrue to women who pursue short-term as opposed to long-term mating strategies. When comparing the five hypotheses, the authors concluded that women in addition to attempting to acquire resources also might

prioritize noncommitted sex as it facilitates current partnership dissolution, fine-tunes skills required for securing a long-term partner, and may secure good quality genes. Prostitution when viewed as a short-term mating strategy would appear to relate only directly to the first of the five classes of benefits outlined. Also, women more inclined toward adopting a short-term or *unrestricted* mating strategy as measured by, for example, the sociosexual orientation inventory (SOI) perceive the benefits of a more promiscuous strategy as being more positive compared to those who score lower (*restricted*). Such perceived benefits include expensive designer clothes, career advancement, jewellery, and access to sex partner's car (Greiling and Buss 2000). This "resource extraction" has long been documented in women, especially in cultures where promiscuous sexual activity has not been prohibited. Malinowski (1929, cited in Workman and Reader 2014) reported that women functioned as mistresses in the Trobriand Islands on the condition that their lover's *provision them with gifts*.

Daddy Issues

One factor that influences the likelihood of women pursuing short-term sexual strategies is the absence of a father during early development. According to Workman and Reader (2014, p.118), "the likelihood of a woman engaging in casual sex relates to whether or not her father was present during her childhood." Arguably, the non-availability of a resource investment role model may predispose women to abandon hope of finding a reliable long-term partner and to realize that archetypically men are only interested in pursuing short-term mating strategies. This may promote the adoption of a quantity over quality mind-set characterized by precocious sexual development and earlier engagement in sex. DelPriore and Hill (2013) found that even when employing experimental procedures (participants were invited to relive periods of "father absence"), college-aged women showed greater activation of sexual concepts, more sexually permissive attitudes, and greater willingness to engage in casual sex and to have more future sex than "father-present"

women. Arriving at firm conclusions regarding the identification of the proximate and ultimate triggers, propelling women to become sex workers is problematic. Father absence, for example, is often associated with a multitude of stress-inducing confounds (Rossler et al. 2010). Future studies may benefit from investigating the probability of "father absence" being evident in "high-class call girls" (sex workers who are more prone to choose sex work as a career).

Sex Ratios

Contemporary evolutionary theories of human mating emphasize the fact that age, contextual, and personality factors contribute flexibly and conditionally to influence the mating strategies adopted at a given time (Buss and Schmitt 2003). One demographic variable that may influence a tendency to adopt a short-term mating strategy is the local sex ratio. South and Trent (2011) found that Chinese men became less inclined to have intercourse with prostitutes and more inclined to engage in noncommercial sex when a high female-to-male ratio was evident. This suggests that opposite-sex partner abundance may increase early, frequent, and multi-partner noncommercial sex possibly restricting the opportunities normally available for women to pursue prostitution as a short-term mating strategy. Sexual dynamics inevitably change in contexts where women outnumber men (e.g., when warfare decimates male populations). Symons (1979) reported that in both the Ache and Yanomamo (cultures characterized by inter-tribal homicide), women appear to pursue short-term strategies in order to secure smaller amounts of resources from multiple partners.

How Much to Charge?

In a free market, the price a woman of one age charges in comparison to another age for sexual services reveals a great deal about both the value assigned to youth by men and the realization by women that they possess what men want. The Internet is an ideal medium to explore sexual behavior due to its nonintrusive method of data

collection. Dunn (2018) accessed an online escort website and sampled fees (incalls and outcalls) advertised by escorts for sexual services across various ages and age groups from five different cultures (the UK, Ireland, Australia, the USA, and Eastern Europe). Apart from Irish escorts advertising outcalls, differences were evident in all sampled countries with younger escorts indicating higher charges on their profile pages compared to older escorts. Female self-perceived short-term mate value appears to peak in mid 20s. The realization by women that this diminishes with age translates into a reduction in advertised fees by older women. A similar pattern was reported by Sohn (2016) with an Indonesian sample. Prices charged by prostitutes of peak age (late teens to early 20s) was more than twice that for prostitutes in their late 1930s. Griffith et al. (2016) found additional traits besides youth to be of importance. That said these were clearly all related to fertility. Lower weight and body mass index, breast and buttock nudity, and idealized 0.7 waist-to-hip ratios (WHR) were all associated with higher fees.

Conclusion

Traditional explanations for the existence of prostitution are challenged when adopting an evolutionary perspective. Differential sensitivity to resource acquisition benefits, demographic factors such as the sex ratio of a given cultural group, personality factors such as father absence, and perceived mate value may all contribute to the predisposition of women to pursue this perhaps most extreme manifestation of a short-term mating strategy.

Protosyntax

Dieter G. Hillert
UC San Diego, La Jolla, CA, USA

Synonyms

[Linear grammar](#); [Linguistic fossils](#); [Precursor to language](#); [Premodern language capacity](#); [Protolanguage](#)

Definition

The term Protosyntax refers in cognitive science to a precursor stage of the human capacity for modern languages. It includes linear phrases with primarily uninflected nouns and verbs.

Introduction

The notion Protosyntax, also called protolanguage or linear grammar, is a possible window to our understanding of how the modern language capacity might have evolved from single words to complex syntactic structures. It typically refers to a hypothetical precursor stage in the language domain, but in principle, it can also refer to other cognitive capacities such as the Protosyntax of music. The linguistic notion implies that language evolved gradually in the hominid lineage from basic to more complex syntactic structures. Protosyntax uses a linear order of words, is non-hierarchical organized, and lacks inflectional morphology. For instance, it does not use inflections for Tense or Case, is based on semantic combinatory principles such as the perceptual strategy (Agent-First), does not form clusters (hierarchical phrases) to generate questions, passive voices, anaphors, or subclauses as found in fully-fledged modern languages.

Protosyntax, as assumed, is a linguistic fossil that mirrors a possible stage in the evolution of language (see for example Bickerton 1981, 1990; Jackendoff 1999; Progovac 2010; Hurford 2012). One possible implication is that our biological relatives such as *Homo erectus* (ca. 1.9–0.3 ma) were equipped with a basic language capacity scaffolding a linear word order but not the morphosyntactic complexity of modern languages. In contrast, the oldest fossils of anatomical modern humans more recently discovered in Morocco are about 300 ky old. Our extinct sister species, the Neanderthals (ca. 700–40 ka), had comparable genetic, neurological, and cultural parameters as modern humans, and thus their language capacity was presumably comparable to modern humans (Hillert 2015). One line of evidence finds these structures in emerging languages (e.g., pidgin or sign languages), another line in how children and adults acquire language, how language breaks down, or how these linear phrases resurface in modern languages. Although speculative, research on Protosyntax is highly relevant for the debate on the innateness and origin of the human language capacity (Fig. 1).

Protosyntax, Fig. 1 The Protosyntactic Stage in Language Evolution

Emerging Languages

Some languages emerge by the contact of speakers of different languages and who are unable to use a mediating language, a *lingua franca*, for communication. In Hawaii, for example, various ethnic groups such as Chinese, Japanese, Portuguese, Koreans, and Filipinos spoke at the end of the nineteenth century different pidgins to communicate with the English-speaking population, the Haole (Caucasians) and the native Hawaiians. Since pidgins are not fully-fledged languages but make use of linear syntactic structures, Bickerton (1990) assumes that a pidgin would reflect a protolanguage spoken of early humans or of other Homo species. The linguistic fossils found in pidgin are, however, sometimes less informative for identifying Protosyntax as pidgins are influenced by the speakers' native languages (e.g., flexibility of word order). Another example is Riau Indonesian, a Malayan dialect spoken by several million people. Virtually, no syntactic categories (nouns vs. verbs) and (almost) no morphology are used, and the word order is based on semantic principles (Gil 2005).

Several newly created sign languages are known, which use a perceptual strategy and lack morphology. One example is home signing. Deaf children create often home signs to communicate with their hearing but not signing parents.

Like spoken language, the children go through a two-gesture stage and their developed home sign system is more complex than speech-supporting gestures. Another example, which is well-known, is the Nicaraguan Sign Language, which previously isolated deaf children created in the 1970s from elements of their own diverse home sign systems. The first generation used signs to refer to objects they needed to talk about and stringed them together in phrases. To describe an event, they would sign each Agent followed by his or her role such as “girl push boy fall” or “boy give girl receive.” The next wave of deaf children elaborated on these structures (Senghas et al. 2004). The emerging sign language Sayyid Bedouin Sign Language (Sandler et al. 2005) and the isolated village sign language Central Taurus Sign Language (Caselli et al. 2014) are similar examples.

Modern Languages

Traces of Protosyntax, sometimes called “living fossils,” can be also identified in fully-fledged modern languages and how they are acquired and break down. Agrammatic aphasic patients, typical with lesions to Broca's area, fall back on a perceptual strategy, drop inflections and function words. Child language acquisition includes

always a two-word and a telegraphic stage, in which inflections and function words are rarely used. Again, second language adult learners without explicit language instructions show across all examined pairs of native and second languages a protosyntactic stage. Genie, a well-known victim of severe child abuse, who was not exposed to language until the age of 13 years, quickly acquired words after she was found, but her grammar remained behind even years after training.

Specific syntactic structures found in modern languages may also be traces of a protosyntactic stage (see Progovac 2010; Jackendoff 1999). For example, verb-noun compounds without a head (*pick-pocket*); noun-noun compounds based on concatenations are pragmatically interpretable (*cheesecake*); free placing of adverbial expressions (*apparently* or *in the morning*) can be in initial, medial, or final position of a clause; or small clauses (*problem solved!*).

The languages so far discussed do not fall all in the same category in terms of morphosyntactic complexity. Modern languages typically use more cognitive resources than creoles or indigenous languages such as Riau Indonesian, which in turn use more resources than emerging languages like pidgins or new sign languages. As we have seen, resources are used to various degrees, but all modern humans are equipped with the cognitive capacity to use these full resources associated with fully-fledged modern languages.

Conclusion

Protosyntax is typically considered as a linguistic fossil, which can be identified in emerging and modern languages, and possibly also in other cognitive domains such as music. This approach, although speculative, is highly intriguing for understanding the cognitive and neurobiological parameters of language processing and how these parameters might have evolved in the hominid lineage. The protosyntactic stage is certainly not the first stage of language evolution as a lexical stage with distinct sound units must precede a syntactic stage. Protosyntax might, however, mirror the premodern language capacity of our

biological ancestor *Homo erectus*. Although alternative scenarios are conceivable, the idea that the “language-ready brain” for fully-fledged modern languages coincides with the birth of anatomical modern humans and their sister species is plausible as is the idea that the “protosyntactic-ready brain” can be associated with *Homo erectus*. To what extent early modern humans or *Homo erectus* respectively used their genetically predetermined cognitive resources is a closely related but different issue. In conclusion, current evidence shows that the modern language capacity could not have evolved without the capacity for protosyntactic structures.

Proto-tool

Ivo Jacobs and Mathias Osvath
Lund University, Lund, Sweden

Synonyms

Borderline tool

Definition

Proto-tools are functionally analogous to tools but are not held and directly manipulated during or prior to use. (Shumaker et al. 2011)

Introduction

An ancient prophecy once foretold that Aeschylus, the Greek playwright, would die by something falling on his head. He therefore spent the entirety of this cursed day in an open field, far from buildings, trees, and anything else that could fall on his head. Alas, he could not escape his destiny because an eagle dropped a tortoise on his head. If the eagle intended to kill him, this would be classified as tool use. However, it is possible she simply aimed for a nearby rock, or mistook the poet's shiny bald head for one, in order to crack the tortoise's hard shell. This would be classified as proto-tool use because the supposed tool (rock or head) was not held or manipulated by the eagle (Shumaker et al. 2011).

Defining tool use is an ongoing challenge that includes distinguishing it from similar behaviors

such as proto-tool use. An essential criterion of tool use is that the tool is manipulated by the user because otherwise the term would be too broad, encompassing behaviors such as climbing trees and living in burrows. Shumaker et al. (2011) emphasize that their distinction is logically rather than biologically meaningful, which others have argued to be arbitrary or anthropocentric (e.g., Shettleworth 2010).

Proto-tools are a subset of borderline tools, although some consider them synonyms. Constructions such as nests, bowers, and dams are made from numerous elements that are considered tools during construction. However, the construction itself is not a tool because it is not held or manipulated in its entirety. Constructions are classified as associative tool use because tools are involved during their creation, whereas tools are never involved in borderline cases. Examples of borderline behaviors are ingesting objects to aid digestion, self-medication, dust bathing, washing or soaking food in water, painting, object play, and pulling prepositioned strings or rakes. Borderline cases demonstrate that tool use is not always a clearly distinct behavioral category (Shumaker et al. 2011).

Fixed Anvils

Many species open encased or hard food items by dropping, throwing, or pounding them against fixed anvils, which is the archetype of proto-tool use (Cristol and Switzer 1999; Lefebvre et al. 2002; Shumaker et al. 2011). Birds such as gulls, crows, and raptors drop mollusks, nuts, eggs, bones, and – in line with the Greek tragedy – tortoises. Throwing or smashing encased foods is a more frequent use of fixed anvils in mammals, especially carnivores and primates.

The best documented type of proto-tool use is food dropping by crows. Mathematical models and dropping experiments predict that walnuts should be dropped from greater heights if the dropping surface is softer; the walnut species is harder; the walnut weight is lower, because heavier walnuts open slightly easier; the walnut has not been dropped before, because they

weaken with every drop; and the risk of theft is lower, when fewer conspecifics are present. American crows dropped walnuts in a manner consistent with these predictions, except that walnut weight did not influence dropping height. Attempted theft by others was frequent, so dropping from lower heights was highly advantageous (Cristol and Switzer 1999).

Similarly, hooded and carrion crows drop mussels onto rocks. Juveniles never succeeded on their initial attempts, probably because they dropped them over softer gravel or mud. On the other hand, adults dropped mussels onto rocky substrates and always succeeded on their first try, which suggests this proto-tool use has to be learnt during development. Adults might have dropped mussels from optimal heights to conserve energy and because there was no risk of theft during this study period. Dropping from greater heights might also shatter and disperse shell fragments farther, which would increase searching and handling time. Crows never selected small mussels. Approximately 22 medium-sized mussels are sufficient to fulfill the daily energy requirement of an adult crow, which illustrates the potential significance of proto-tool use (Davenport et al. 2014).

New Caledonian crows frequently use various tools in their natural habitat, and they crack nuts by placing them against a forked branch and then dropping them on rocks below. Certain nut-cracking sites are communally used, probably because exposed rocks are rare in their habitat. Dropping nuts from a branch might be more accurate than from flight, especially when the hard surface is relatively small. It also appears to facilitate finding a suitable dropping position in three-dimensional space, which reduces energy expenditure and risk of theft, although this was never observed. This technique may have originated from caching, because crows sometimes store nuts and tools in tree forks. Other possible explanations are that it is more effective in opening them, increases the predictability of success, or reduces time spent selecting and testing suitable locations (Hunt et al. 2002).

New Caledonian crows also secure nuts in crevices or holes and then force them open with

their beaks. These *vice-anvils* combine the properties of anvils (hammering support) and vices (restricting movement). After successfully opening nuts by dropping them on rocks below, they placed them in depressions on a fallen log to stabilize them while extracting kernels. Rooks, a crow species that does not naturally use tools, placed walnuts on fence posts or tree branches to open them. This occurred so frequently that the wood slowly eroded away, leaving clear walnut-sized depressions that presumably increase the efficiency of these vice-anvils (Hunt 2014). Vice-anvils are also used by other birds, such as woodpeckers and nuthatches. Shrikes and butcherbirds employ a different method: they secure prey by impaling it on thorns (Lefebvre et al. 2002; Shumaker et al. 2011).

It was often thought that the main reason why American crows drop walnuts on roads is so cars can crack them, but apparently they do so because the road surface is hard, and cars rarely drive directly over the walnuts. Crows also frequently dropped walnuts on other hard surfaces that vehicles could not reach, such as rooftops and sidewalks. Relying on cars as nutcrackers might even be disadvantageous because the resulting small food pieces cannot be monopolized, and bird species that do not drop walnuts might attempt to steal them (Cristol et al. 1997). Nonetheless, carrion crows in Japan put walnuts in front of cars waiting at traffic lights. This behavior seems to have originated at a driving school and spread over several kilometers the following 20 years (Nihei and Higuchi 2002). These roads had heavier traffic than the American study site, which may not have provided sufficient opportunity for the American crows to develop this behavior.

How Different Is Proto-Tool Use from True Tool Use?

Some species use both true and proto-tools. Sea otters, capuchin monkeys, and chimpanzees pound nuts and mollusks against stones and use stones to hammer them open (Shumaker

et al. 2011). Similarly, Egyptian vultures throw eggs onto rocks and rocks onto eggs. They throw pelican and flamingo eggs but they cannot easily grasp larger eggs so they use tools to break them. In one study, young vultures were not strongly interested in ostrich eggs until they fed from one. One juvenile spontaneously started to drop stones on an artificial ostrich egg after this experience without having seen others do so. Its accuracy quickly improved, but even experienced adults make direct hits in only half of their attempts. Neither is their tool selection optimal; both juvenile and adult vultures sometimes select ineffective objects such as wood, dung, or small stones (Thouless et al. 1989).

It has often been hypothesized that true tool use (dropping stones onto eggs) develops directly from proto-tool use (dropping eggs onto stones). Indeed, both wild and hand-raised Egyptian vultures prefer to drop round stones that resemble eggs. They select and manipulate stones as if they were pelican or flamingo eggs, and instead of throwing the object held in their beaks onto stones, they throw it at ostrich eggs, using identical movement patterns. Another explanation is that when vultures encounter an egg that is too large, they redirect their behavior to nearby stones as conflict behavior. The vulture might then accidentally break the egg, which would lead to an association that is repeated in the future and could eventually become a habitual species-wide behavior through social learning (Thouless et al. 1989).

Birds that use true tools have on average a relatively larger brain than those that only use proto-tools. This supports the idea that true tool use is more cognitively complex. The rate of feeding innovation is correlated with proto-tool use, and both are suggested to be an expression of behavioral flexibility. There is also a positive relationship between relative brain size and tool use in primates, but proto-tool use was not analyzed (Lefebvre et al. 2002). However, both true and proto-tool use are broad categories that might overlap, and some proto-tool users have relatively larger brains than true tool users (Shumaker et al. 2011).

Conclusion

The difference between proto-tools and true tools rests only in manipulation. Contrary to common assumptions, this does not necessarily mean that proto-tool use is more primitive, always arises earlier in development, or forms an evolutionary precursor to true tool use (Shumaker et al. 2011). Although they are sometimes viewed as identical categories based on associative instrumental learning (e.g., Shettleworth 2010), this should not be presumed without further study. The cognition, development, and evolution of proto-tool use should be investigated in its own right and not be merely inferred to be simpler or less important than true tool use. Dropping food onto hard surfaces is a complex functional behavior, and tool use might not increase its efficiency. After all, dropping food to open it is easier than aiming for someone's head for a killing blow.

Definition

Theoretical framework defining the major axes of variability of the life history strategies across the tree of life.

Introduction

The diversity of living forms on Earth is only paralleled by the heterogeneity of their life history traits, such as their longevity or growth rates, which can vary several orders of magnitude. From microscopic *Escherichia coli* to large blue whales (*Balaenoptera musculus*), species show a great

deal of variation in numerous traits that are inexorably linked to their success on earth's environments. Despite such a great diversity, all living creatures experience the same demographic processes of survival, development, and reproduction. The variation of these key demographic processes in timing, intensity, duration, and frequency defines important life history traits (e.g., age at maturity, net reproductive rate, etc.), and the combination of these life history traits results in life history strategies (Stearns 1992). Life history strategies ultimately determine the dynamics of the species, and they are the result of different evolutionary and ecological processes.

Why Is There So Much Life History Variation?

The course of evolution has sculpted a myriad of life history strategies, with planktonic organisms living for few years, while the Pando aspen clone in Utah (*Populus tremuloides*) can live up to 80,000 years. At first glance, one may wonder, why are all species not immortal and produce high numbers of progeny at a time? The response is the existence of “boundary conditions” (*sensu* Stearns 1992) that constrain the available combinations of life history traits. These constraints can be classified as *extrinsic* or *intrinsic*.

Extrinsic life history constraints are those imposed by the surrounding environment. Such life history constraints depict whether the extrinsic environment favors certain strategies but not others. For example, there are no strictly sessile animals on land, while this strategy is rather common in aquatic animals. In this case, the environment has likely enabled the evolution of sessile organisms that feed on the suspended material lying in the water column. Here, the surrounding environment not only refers to the physical one, but also the intra/interspecific interactions. For example, predation has a high influence on the life history of guppies (*Poecilia reticulata*) in Trinidad. Under high predation rates, guppies show higher densities, slower growth, with populations dominated by young, small individuals (Reznick 1982).

The *intrinsic constraints* to life history strategies, on the other hand, are related to the genetic material, as well as physiological, behavioral, and

demographic traits. Evolutionary history or phylogenetic ancestry plays a key role in determining the potential adaptations that a species has. Genetic material is transmitted from parents to descendants, and this nexus can determine the traits available to the latter ones. Heritable traits also set the limits to the evolutionary changes that can be achieved in the short term, and potentially at long term. For example, birds are more likely to have adaptations to optimize their flight than a mammal, with the exception of bats (order Chiroptera).

Intrinsic relationships between traits are commonly referred to as trade-offs. These budgetary compromises between investing resources in one trait/biological function at the expense of others are grounded on limiting resources (Stearns 1992). There are physiological constraints to the amount of energy that an organism is able to invest in one particular trait or biological function. The linkage between traits implies that the evolution of certain life history traits (e.g., high reproductive output) will have implications for others (e.g., adult survival). Thus, the fitness benefit through increasing a given trait must be balanced against the fitness cost of decreasing another trait. Overall, this means that not all life history components can be maximized simultaneously.

Life History Theory

The fascination for the vast diversity of living forms on earth has captivated many biologists. The quest of these scientists to reveal the causes and consequences of the variation in the life history strategies of species across the tree of life gave birth to the disciplines of evolutionary ecology and life history theory. Historically, life history evolution has been approached from the lens of problem optimization. That is, species are selected to evolve the life history strategy or strategies that maximize their fitness according to their evolutionary history and their surrounding environment. However, infinite combinations of strategies cannot evolve. This is, partly, due to the fact that life history traits covary, and it is possible to define major axes of life history variation. Thus, a given pool of traits characterizing different demographic processes can be reduced to fewer

n dimensions along which species can be classified.

There have been several attempts to unveil the major axis of life history variation. Pioneer Robert MacArthur proposed that species could be classified as organisms, type A or type B, in a similar way to the chemistry's periodic table of elements (MacArthur 1972). That is, to order species according to a set of life history attributes, as the chemical elements are classified by a combination of their atomic number (protons), configuration of electrons and certain chemical properties. Later on, Eric Pianka formalized the concept as "periodic table of ecological niches" (Pianka 1970), a scheme that organized species or organisms based on their similarity, as defined by a set of functional traits associated with various niche dimensions. During the consolidation of life history as an ecological discipline, the classification of life histories diverged into several schools, including plant scientists, animal scientists, and bacteriologists. Here we provide a subset of the main frameworks with relevant contributions to the development of life history theory.

r-*K* Strategies

One of the first attempts to classify species according to their life history strategies was the *r*-*K* strategies framework by Pianka (1970). In his seminal paper "On *r* and *K*-selection," Pianka suggested classifying organisms along a continuum of strategies with two extremes. The *r*-endpoint represents the extreme where species are highly reproductive, reproduce early in life, and have rapid development and small body sizes. On the other hand, at the *K*-endpoint, species are less reproductive, with late reproductive maturity and have slow development and large body sizes. For example, he suggested that vertebrates were *K*-selected species, while most insects were *r*-selected.

Pianka also developed the concept of *r*-*K* selection, relating species life history strategies with environmental conditions. This theory predicts that fluctuating environments with high environmental stochasticity and no density-dependence or limited competition (reduced population size), favor those species with traits maximizing productivity (here

population growth, *r*), *r*-strategies. In contrast, under conditions of high competition and density-dependence but with more environmental stability, species with traits that were more efficient in the use of resources and maximize the equilibrium population size were favored (*K*, carrying capacity), *K*-strategies. This principle was then linked to ecological succession. After a major disturbance, ecosystems experience a release of competition and new resources are available. Species colonizing such habitats will be favored when they have high values of *r*-traits. The “rapid” colonization of the habitat would be followed by its own saturation, increasing the number of individuals and then the competition. Under such saturated conditions, organisms that are more competitive at extracting energy from the habitat would then be favored. That is, phenotypes with a high *r* will be selectively favored at low densities/high resource conditions; while those with a high *K* at high densities/low resource conditions.

The dichotomous classification of species being either *r*- or *K*-selected gained both adepts and detractors. Perhaps one of the most insidious criticisms was provided by Stearns in extensive reviews about the life history theory (1992). One of his main critiques was that the *r*-*K* dichotomy did not provide an explanation for the underlying demographic mechanisms regulating populations. The lack of mechanistic explanations was indeed especially concerning, since different life cycle stages (e.g., young vs. adult) typically suffer differently the consequences of density-dependence. These, among other major flaws, caused a loss of popularity for the *r*-*K* paradigm. However, not much time elapsed till the empty niche was filled with newer life history frameworks.

Extending the *r*-*K* Dichotomy: The Fast–Slow Continuum

Following his critical essay to the *r*-*K* dichotomy, Stearns proposed a new life history framework (Stearns 1992). By empirically analyzing a set of life history traits from different mammal species, he showed that both body size and phylogeny had significant influences on life history strategies. In his framework, Stearns states that life history strategies vary according to how species invest

energy in maintenance, development, and/or reproduction. Accordingly, organisms may range between being *fast*, highly-reproductive but short-lived, to *slow*, long-lived, and rarely successful at recruiting. This axis of life history variation empirically evidenced an already known life history paradigm, the existence of a trade-off between survival and reproduction. The coined *fast–slow* continuum, opposed to the *r*-*K* framework, included the influence of body size and phylogenetic relationships on life histories (Stearns 1992). Importantly, this continuum also accounted for physiological limitations and trade-offs, a missing block in Pianka’s life history tenet.

The *fast–slow* continuum still has several limitations that remain to be resolved. First, the underlying ecological factors determining life history variation are still unclear. Besides, a rather controversial fact with the *fast–slow* continuum is that it only accounts for barely half of the life history variation. This flaw was indeed pointed in some early seminal works (e.g., Gaillard et al. 1989), which identified an important second axis related to reproductive traits in birds explaining additional rates of variation. His work suggested that species could be *fast* or *slow* in different ways, revealing that more axes of variation may be needed to fully capture the life history of species.

Beyond Dichotomies: The Fast–Slow and Reproductive Strategies

Despite the usefulness of the aforementioned frameworks, these classifications of life history strategies were limited in geographic, taxonomic, and phylogenetic scales and in the ability to differentiate life history trade-offs. However, these major drawbacks are currently being overcome with the growing body of demographic data. Salguero-Gómez (2017) recently analyzed the demographic trade-offs of 650 vascular plant species across biomes and accounting for the phylogenetic relationship of the species included. He identified two major dimensions of demographic variation: the well-established *fast–slow* continuum and a novel reproductive strategy dimension. The main achievement of this framework is that it reconciles the life history frameworks only focused on one single life

history axes of variation, such as the *r-K* or the *fast-slow*, with those begging for a “beyond K” axis of variation (Stearns 1992; Southwood 1988; Gaillard et al. 1989).

Another novelty of this framework is that it transgresses different ecological scales (Salguero-Gómez 2017) and kingdoms (Paniw et al. 2018). Because of the demographic basis of the *fast-slow* and reproductive strategies, and thus based in allocation strategies, this framework linked the population level demographic rates with the functional traits that constrain individual performance and fitness. That is, this framework shows connections between the position of species in the *fast-slow* and reproductive strategies to species’ functional traits (the leaf economics spectrum), biogeographical characteristics, to their rates of senescence and to their conservation status (Salguero-Gómez 2017). This establishes a nexus between the demographic trade-offs and the “real-world.”

Conclusions

Unlike other scientific disciplines like physics or chemistry, few universal laws have been formulated transcending all hierarchical levels in biology. MacArthur’s vision of a life history periodic table pointed the direction towards which a substantial fraction of life history theory has developed during the last decades. Despite the flaws of the *r-K* selection schema, this framework triggered the development of many different and complex life history tenets. Still, life history theory has only scratched the surface of what a “periodic table of life histories” framework may offer to subdisciplines like ecology, evolution, or conservation science. Life history theory should aim to provide a better understanding about the complex imbrications within different scales of biological organization. How can inter- and intraspecific variation in traits can be incorporated in such a periodic table? How do life history strategies determine the behavior of individuals? Are there other important axes of life history trait variation? How can we link the position within the periodic table to species’ responses to climate change? Despite all of the challenges that remain ahead, MacArthur’s dream is still pursued by many

scientists, aided by the increasing availability of high resolution demographic data across the tree of life.

Definition

Interdisciplinary field of study based on evolutionary, comparative, and psychiatric principles employed for the assessment and treatment of behavioral disorders in nonhuman apes.

Introduction

There are currently eight living species of great apes (family Hominidae), classified in four genera, including chimpanzees (*Pan troglodytes*), bonobos (*Pan paniscus*), gorillas (*Gorilla gorilla* and *G. beringei*), orangutans (*Pongo pygmaeus*, *P. abelii*, and *P. tapanuliensis*), and humans (*Homo sapiens*). Genetic analyses have revealed that *Homo* and the two species of *Pan* are the most closely related, collectively sharing more than 98% of their genomes, more than any of them share with *Gorilla*, the next most closely related taxon (Waterson et al. 2005). Given these extensive similarities and the shared phylogenetic history, there is a reason to believe that there are also continuities in the evolution of cognitive and emotional functioning between human and nonhuman apes, including the presence of homologous psychopathological conditions. However, without access to verbal reports of subjective distress, research efforts into psychopathologies in nonhuman primates have been restricted to a purely descriptive level, mainly stemming from observations and experiments conducted with captive individuals (Brüne et al. 2006). Insights from the results of early studies by Harlow on the devastating effects of social deprivation on monkeys (Harlow 1965) prompted adoption of policies to ensure avoidance of total isolation on primates raised in captivity, improving outcomes in many cases.

All great apes are characterized by long life-spans, relatively large body sizes, and complex cognitive abilities. Different species, however, exhibit widely different social organizations. Chimpanzees and bonobos exhibit high levels of fission-fusion dynamics; individuals belong to communities with stable memberships that collectively use and defend a territory but flexibly form

temporary subparties that differ in size, composition, and duration (Goodall 1986). Gorillas have stable multifemale groups with either a single or multiple adult males, Orangutans lead mostly semi-solitary lives but at the regional level can be described as having an individual-based fission-fusion system (Van Schaik 1999). Regardless of species and social organization, all great apes are obligatorily social, forming, at a minimum, a robust social relationship between mother and offspring during a prolonged period of infantile and juvenile dependency.

Inappropriate living conditions such as social, sensory, and/or motor deprivation, especially in barren and uncontrollable environments, appear to lead to a variety of behavioral abnormalities, including “an inability to copulate, incompetent maternal behavior, inappropriate emotional reactions—mainly fear and aggression—to companions, lack of species-typical communicatory signals, and generalized learned helplessness” (Brüne et al. 2006, p. 1249). Additionally, captive individuals have been observed to engage in numerous behavioral patterns that are abnormal in their frequency, severity, or gross anomaly, including bizarre postures, hand clapping, hair pulling, rocking, regurgitation, and re-ingestion of food, and many others (Brüne et al. 2006).

In free-living environments, away from overtly artificial contexts, manifestations of psychopathologies in apes have been limited to speculative anecdotes, primarily due to an incomplete knowledgebase of the full range of “behavioral normality” and a means of assessing distress or disorder. While reports abound of individuals appearing to behave more lethargically with a depressed appearance after experiencing the death of a close companion (typically one’s own offspring or mother), there is limited evidence of quantifiable distress.

Measurement Challenges and Potential Solutions

While a greater understanding of mental health in great apes could allow us to treat captive apes better and lend insight into the evolutionary

origins of psychopathology in humans, attempts to measure mental disorders in nonhuman primates face two significant challenges: (1) effectively defining “disorder” and (2) measuring the mental states of great apes. Finding a generally agreed-upon definition of pathology, especially for mental illnesses, has been a challenge which clinical psychologists and psychiatrists have still yet to remedy in humans. The problem of measuring the internal psychological states of apes is common to all approaches which seek to understand cognition in nonverbal animals.

Some researchers have attempted to adapt the American Psychological Association’s *Diagnostic and Statistical Manuals of Mental Disorders* (DSM) directly to assess the equivalents of mental disorders in apes, symptom by symptom (e.g., Ferdowsian et al. 2011). The DSM is currently on its fifth edition, and with each cycle of revision, the definitions of mental disorders are altered and often expanded. One issue with this is that expanding definitions could lead to “disorder creep,” increasing the proportion of individuals characterized as expressing pathological behavior.

Studies on comparative psychopathology are confronted with the issue of adequately defining concepts such as disorder and maladaptation. Clinical psychology and psychiatry employ these terms to describe an alternation of mechanisms regulating physiology, cognition, behavior, and affection, with treatment being aimed to restore the mechanism to its original state before the disruption. At the ultimate level, however, maladaptation refers to a fitness loss due to an organism’s phenotype (Del Giudice 2018). This distinction is crucial when considering behaviors that at first hand seem maladaptive but after further examination reveals the trait increases the organism’s fitness. The study of infanticide by males, for example, was at initially described as the outcome of pathological behavior. This position, however, has been abandoned and replaced with an adaptive hypothesis wherein the attacker attains fitness benefits by killing younglings (Troisi 2003).

One possible solution to the problem of defining disorder is to use Darwinian fitness as a metric, where evolutionarily adaptive traits are

considered “normal” and maladaptive traits are considered “abnormal” or pathological. In this scenario, ape behaviors which are associated with fitness losses compared to normative behavior would be considered as symptoms of a disorder, a breakdown of neural mechanisms which evolved to deal with specific scenarios but cease to function in other contexts.

While the evolutionary approach to defining “disorder” shows promise, adaptive significance can prove difficult to demonstrate for complex traits such as mental illnesses which are often characterized by a combination of many traits with varying heritability. The evolutionary definition also does not align with accepted human-specific definitions of disease which comprise sociocultural layers of meaning and often include context-specific definitions of “function” and “dysfunction.” Because of this misalignment, comparing across humans and other great apes using this approach could generate challenges. Nonetheless, taking an evolutionary perspective could be used in conjunction with definitions of pathology which include the statistical rarity of behavior, and the observation of stereotypes, especially given any individual’s known traumatic history. Because many human-specific definitions of psychopathology include a criterion of interference with daily life, applying a criterion related to function and disruption could create a useful area of overlap to compare humans and other apes.

Homologous Features in Individual Differences and Expression of Behavioral Symptoms

Although ethological research in individual differences had been conducted before the decade of the 1990s, few studies attempted to directly adapt instruments used for the assessment of individual differences to other species. King and Figueredo (1997) were among the first to hypothesize that chimpanzees would exhibit a personality structure akin to that of human participants. The authors generated a list of 43 adjectives associated with the personality traits described by the five-factor

model (i.e., conscientiousness, agreeableness, neuroticism, openness to experience, and extraversion). The factor analytical procedure not only extracted the hypothesized five personality factors but it also found a sixth dominance dimension, a trait absent, in the five-factor model of human personality (King and Figueredo 1997). Following this publication, psychometric research has consistently revealed parallels in the factorial structure of personality between human and great apes (Brüne et al. 2006).

The presence of similar, albeit not identical, personality dimensions in nonhuman primates, encouraged researchers to adapt several human self- and peer-report instruments used for the diagnosis of various psychopathologies. Researchers proceed to examine the validity, reliability, and factor structure of questionnaires employed for the assessment of personality disorders. Psychopathy inventories were developed to examine the degree of behavioral disinhibition, risk-prone, and antagonism. These measures presented adequate inter-rater reliabilities and were correlated with observed behaviors (Brüne et al. 2006). Furthermore, additional examinations of a triarchic model of psychopathy, based on dimensions such as boldness, meanness, and disinhibition, indicate these characteristics, has been found to that akin to human samples, display low to moderate heritabilities (ranging from 0.36 to 0.65; Latzman et al. 2017). Moreover, these analyses found evidence supporting the presence of a single higher order psychopathy factor, with a heritability of 0.64.

Behavioral and Psychopharmacological Interventions

Concerning treatment, studies examining the effectiveness of environmental enrichment concluded that enclosures facilitating cognitive stimulation, as well as encouraging physical activity decreases the frequency of stereotypes (Brüne et al. 2006). Similarly, behavioral intervention based on operant conditioning has also been found to decrease the frequency of regurgitation temporarily. However, there is still debate

concerning the long-term success of these procedures. In cases of regurgitation, for example, some evidence suggests this pathological behavior may reemerge months after the intervention stopped (Brüne et al. 2006). Even though compulsion, frequently observed in human patients suffering from OCD, could be hypothesized to share some features with stereotypies in nonhuman primates, it remains to be tested whether these aberrant behaviors are correlated with other manifestations of distress homologs to human psychopathologies (e.g., mood disorders or other anxiety disorders). It is relevant to notice that although most of these repetitive, functionless behaviors, have been observed in captive conditions, one must be cautioned against the oversimplification of equating “wild” with “normality” and “captive” with “pathology” (Brüne et al. 2006), particularly in light of the fact that not all captive individuals exhibit such aberrations.

Resocialization is also considered a potential avenue to assuage behavioral and affective disturbances, especially in cases where the individual grew in isolation of experienced trauma. The process can extend from weeks to months, with varying degrees of success depending on the type of pathological behavior and the temperament of the individual. Even though psychopharmacological interventions, for example, prescribing serotonin reuptake inhibitors, have been used to treat motor stereotypies, aggression, and self-mutilation, additional research is necessary to determine the level of effectiveness of these treatments. Future studies should also examine the degree to which the reduction of symptomatology is a product of each intervention or the interaction between treatments. Similarly, it remains to be seen whether these drugs produce similar side-effects, in great apes, as in humans. Some of the reported cases complemented the pharmacological treatment with behavioral interventions (Brüne et al. 2006).

Conclusions

Due to their phylogenetic proximity with modern humans, great apes had been hypothesized to display parallel manifestations of individual

differences, such as personality traits, and display similar signs of underlying pathologies. An array of methods had been employed to determine the presence of psychopathological features, from ethological observations to the adaptation of inventories. Although preliminary evidence suggests commonalities between human cognitive and behavioral disturbances, with that observed in disturbed individuals of other species, additional research is needed before concluding the presence of psychopathology. In addition to the challenges associated with diagnosis, a little research has been conducted on the efficacy of interventions such as psychopharmacological treatments have on behavioral abnormalities.

Cognitive universals; Human nature; Human universals

Definition

The “psychic unity” idea denotes the existence of a set of psychological and cognitive capacities universally shared by human beings and grounded in biological equality.

Introduction

The psychic unity idea assumes that all humans share cognitive and linguistic capacities that are grounded in biology and that uniformly underlie how we relate to one another and to the world we live in, regardless of differential cultural upbringing. This chapter is divided into three sections. In the first section, we detail how the idea originates in ancient Greek philosophy and how throughout the ages it has spread toward the different

sociocultural and linguistic disciplines. In the second part, we discuss how today, researchers in the cognitive, behavioral, and cultural sciences are providing a new biological foundation to the search for human universals. And in part three, we point toward current debates on the nature and tenability of the idea of a psychic unity.

History of the Concept

The psychic unity idea, or the idea that there exists an essential and uniform human nature made up of shared sensorial and reasoning capacities sometimes rendered with the notions of a “shared human nature” or “human universals,” has its roots in ancient Greek philosophy. Subsequently, it has spread throughout Western philosophical, religious, and humanist thought where it has been reinterpreted multiple times over. Common to all notions of a psychic unity is the adherence to assumptions on shared cognitive, cultural, and linguistic capacities which are contrasted from notions of particularity and relativity of such capacities.

The Philosophical Origins of the “Psychic Unity” Idea

Plato (428/427–348/347 BC) and Aristotle (384–322 BC) are among the first to argue that all beings have an essence that makes them into what they are. On their account, what makes humans “human” is their intellectual soul that enables them to reason (Gontier 2009). By making use of their reasoning skills, humans are able to distinguish truths from falsehoods, whereby falsehoods are “bad” judgments informed by the use of the senses and truths are “good” judgments that rely on the use of the intellect. At night, for example, we falsely “perceive” the objects around us as black or gray, but we “know” that in truth, they have colors. But although differences in judgment occur due to making judgments either based upon reason or upon the senses, these thinkers assume that all humans are equipped with the same reasoning and perceptual capacities enabling them to make judgments in the first place.

Early Judeo-Christian thinkers agree that all human beings are endowed with both intellectual and instinctive capacities. For them, the intellect is a divine gift, while instincts are inspired by evil. Following one's reason or one's instincts becomes a matter of "free will," and differences in judgment result from choice inspired by faith or lack thereof.

From the seventeenth century onward, rationalists such as René Descartes (1596–1650) continue to endorse that all humans share a "universal reason" that they receive from a benign god, while empiricists such as John Locke (1632–1704), George Berkeley (1685–1753), and David Hume (1711–1776) introduce the notion of a "common sense" grounded in a universal way of perceiving the world through the senses. In so far as differences in reason exist, these are now understood to be of a cultural rather than a psychological kind (Gontier 2006, 3).

The encounter of non-Western nations with different cultural traditions makes moral philosophers such as Thomas Hobbes (1588–1679), Jean-Jacques Rousseau (1712–1778), and Adam Smith (1723–1790) distinguish between an individual or natural state wherein all human beings are equal and a societal or cultural state wherein linguistic, social, economic, and political differences exist (discussed in Gontier 2009). Due to a growing awareness of natural history, differences between societies and cultures are subsequently understood as resulting from an "unequal development" of common capacities along a hypothesized gradient of stadial socio-cultural development that mimics the history of Western society, from hunter gathering over agricultural to industrial societies (Ingold 2006, 266).

Human Variation in Times of Biological Racism

In natural history studies and the early biological sciences, the encounter of non-Western cultural groups results in early attempts at explaining biological differences in terms of species variation. Carl Linnaeus (1707–1778) is one of the first scholars to divide the human species into five

varieties: "Americans," "Europeans," "Asians," "Africans," and "Monsters." For the last category, Linnaeus draws upon a combination of false mythical tales as well as more concrete reports of humans with birth defects. The first four categories are based upon variation in physical features and geographical location, as well as assumed cultural temperaments which corresponds to what we would call stereotypes (Gould 1981).

Differential psychological and cultural traits thus become understood as biologically innate. And together with the varied physical appearance of human groups and their differential geographical dispersal, these traits become a means to debate unity and variation within our species. Scholars are thereby split into two camps. Georges-Louis Leclerc, Comte de Buffon (1707–1788), Johann Blumenbach (1752–1840), and James Cowles Prichard (1786–1848) maintain that all humans share a single origin (monogenism), while Charles White (1728–1813), Christoph Meiners (1747–1810), Thomas Jefferson (1743–1826), and Georges Cuvier (1769–1832) assume that the human species can be divided into varieties or "races" that each have historical origins independent from one another (polygenism).

In this regard, Charles Darwin (1809–1882), the founder of evolution theory, claims that behavioral traits and variation thereof are the outcome of evolution and that all humans share common descent with modification (monogenesis). But Darwin (1871) also endorses the false view that human varieties can be divided into "races" with morphological, psychological, and cultural differences that Darwin (1871) differentiates "races" morphologically, by different bodily characteristics (what we today call phenotypic differences), but also psychologically, by assuming differences in mental capacities and character traits, and culturally, by assuming different levels of "civilization." He furthermore assumes that these traits can be classified along progressive scales that bear connotations as going from "inferior" to "superior"—an idea that is further developed by Ernst Haeckel (1834–1919) with his biogenetic law.

The Search for Universals in the Rising Psychological and Cultural Sciences

The biological racism of the eighteenth and nineteenth century becomes systematically countered by rising psychological and anthropological schools of thought that again reinforce the idea of a psychic or mental unity among mankind. Going back to Immanuel Kant's (1724–1804) concept of pure reason and Johann Gottfried Herder's (1744–1803) idea of historical particularism, Theodor Waitz (1821–1864), Edward B. Tylor (1832–1917), and the ethnologist Adolf Bastian (1826–1905) argue for the existence of universally shared mental capacities (cf. Shore 2000; Jahoda 2013). Bastian (1881), in particular, distinguishes *Elementargedanken* or “elementary ideas” which are universal, fundamental, and timeless psychological structures whereby all humans organize experiences, from *Völkergedanken* or “folk ideas” which are historically particular and culture-specific ideas shared only by members of the same group. The group therefore has a form of social group mind which he calls a *Gesellschaftsseele*.

Franz Boas (1856–1942), father of American Anthropology and student of Bastian, uses the idea of a psychic unity of humankind in his long battle against biological racism. Echoing Rousseau, Boas reintroduces the nature-culture divide and distinguishes between particular *cultural traditions* rooted in different histories and universal, biologically underpinned *mental endowment* brought about by biological evolution (Shore 2000, 91–92). Humans are assumed to be biologically equal in having evolved the same and universal mental capacities that enable them to become cultural beings, while particular cultural traditions result from historical particularities and contingencies.

Ideas of Psychic Unity in (Anthropological) Linguistics

Moving forward to the twentieth century, Edward Sapir (1884–1939) and Benjamin Lee Whorf (1897–1941), two linguistic anthropologists of the Boasian school, further couple the doctrine of psychic unity with ideas on cultural relativism, and they introduce the latter into the study of

language. While also retaining the idea of biological equality in psychological capacities, both Sapir (1929) and Whorf (1956) argue that the way wherein people conceptualize knowledge on the world is always relative to or even determined by the language they speak, so much so that languages underlie worldviews or specific views of the world, a view first introduced by Wilhelm von Humboldt (reviewed in Foley 1997, 197–201).

Sapir and Whorf's anthropological ideas on language also influence the general field of linguistics where, inspired by Eric Lenneberg's (1921–1975) notion of a “critical period” wherein language needs to be learned in order for it to be within the normal range, Noam Chomsky (1928–) subscribes to the existence of a biologically grounded faculty of language. This internal or I-language is characterized by a universal grammar (UG) and opposed to an external or E-language that is particular per individual and language. The former is grounded in biology and the latter in the language community where one forms part of.

In the beginning of the twentieth century, research on universal mental categories would furthermore start to include taboo concepts, kinship distinctions, color categories, etc. Regarding color categories, Brent Berlin (1936–) and Paul Kay (1934–), for example, and by continuing stage thinking and assuming the existence of ladders of complexity, famously argue that there are primary and universally shared color categories grounded in shared perception and that there is a nonrandom sequence in which cultures develop words to express these colors. Such research has nowadays evolved into the fields of folk psychology.

The Biological Foundations of the Idea of Psychic Unity

Today, we know that although humans vary phenotypically, we share the same genes, and the genetic distance between individuals, which is calculated to be 0.2%, is the same for everyone (Cavalli-Sforza 2001). In other words, genetic

differences are too minimal to divide the human species into races, and the different phenotypes we can distinguish are mere variations of the same kind of human. The neurological and cognitive sciences moreover demonstrate that all humans develop similar brain structures, and all normal individuals go through similar developmental stages.

Although there is general agreement on the fact that humans are endowed with alike cognitive structures, scholars are currently debating over which capacities are innate or instinctive and which are acquired or learned during development. On the one hand, *instructionists* maintain that our psychological and behavioral dispositions are acquired over the course of life through learning. On the other hand, *nativists* hold that both our basic physical-biological traits and our psychological structures are innate (Samet and Zaitchik 2017).

In the cognitive sciences, nativist and instructionist approaches go hand in hand with modular and anti-modular or domain-general conceptions of the mind. According to the modular or “mental organs approach,” introduced by Chomsky (1980) and further elaborated by Jerry Fodor (1983), the mind is made up of many genetically determined domain-specific modules or mental organs (Samuels 1998, 577–579; Samet and Zaitchik 2017, 7). On the other side of the spectrum, inspired by Jean Piaget, supporters of the anti-modular approach endorse that our innate cognitive capacities are general purpose (Samuels 1998, 575).

Today, from generative linguistics to universalist cognitive science, from evolutionary psychology to universalist cultural anthropology, a number of contemporary scholars work under the assumption of *evolved and therefore innate* mental competences to substantiate their universalist claims.

By drawing upon Chomsky’s work on UG, generative linguists seek to discover “the cognitive (and hence universal) foundations of language” (Haspelmath 2012, 92). In doing so, they maintain that human beings share a distinct “language faculty” or “innate specialization for language.” On this view, languages differ only

superficially from one another, while on a deeper and structural level, they share a common set of syntactic rules.

Contrary to Chomsky, Joseph Greenberg, the father of linguistic typology, maintains that the existence of linguistic universals can only be deduced from the comparative analysis of many languages. By analyzing the structure of 30 languages, Greenberg (1963) has demonstrated that there exist various types of universals, some “absolute” and some others “statistical.” Among the former, “unrestricted absolute universals” appear true of all languages (i.e., all languages have names and verbs, and all languages have vowels) and come close to the universals recognized by generative linguists (Evans and Levinson 2009, 437–438).

The idea of a psychic unity of humankind is also central to evolutionary psychology. Evolutionary psychology propounds a new “coherent framework for thinking about human nature and society” (Tooby and Cosmides 2005, 16), by maintaining that “a scientific definition of human nature” should focus on “the uniform architecture of the human mind and brain that reliably develops in every *normal human* just as do eyes, arms, a heart, and so on” (Tooby and Cosmides 1992, 209; quoted in Buller 2005, 428).

Examples are the study of *innate* or *evolved* mental competences in how we read other’s behavior (folk psychology) or how we cognitively classify biological species (folk biology). As Scott Atran (1998, 567), who studies folk biology, explains “taxonomies plausibly represent ‘modular habits’ of the mind, naturally selected to capture recurrent habits of the world relevant to hominid survival in ancestral environments.” Within this perspective, cognitive universalism and cultural particularism are ultimately reconciled: a universal system of classification is seen to underlie the development of different cultural classification systems. Evolutionary psychologists, such as David Buss, Leda Cosmides, Martin Daly, Steven Pinker, Todd Shackelford, Valerie Starratt, John Tooby, and Margo Wilson, identify human nature with the idea of a psychic unity of humankind which they define as “a set of psychological adaptations that are presumed to be

universal among, and unique to, human beings” (Downes 2018) (cf. Tooby and Cosmides 2005, 39). On this view, psychological adaptations are evolved psychological mechanisms (Starratt and Shackelford 2010, 235) or modules (reviewed in Downes 2010, 244) that originated between 1.8 million and 10,000 years ago during the Pleistocene Epoch and that helped our ancestors to deal with a number of adaptive problems (Starratt and Shackelford 2010, 231–235; cf. Downes 2018). As Starratt and Shackelford (2010, 232–238) point out, although such psychological mechanisms evolved to respond to inputs present in our ancestors’ environment and although such mechanisms are genetically hardwired and did not change over the last 10,000 years, their output is far from being “staunchly predetermined,” as our behavior is also variously influenced by the environments that we currently inhabit. Along these lines, by claiming that individual variation emerges from “a common nature” attending to different inputs or circumstances, evolutionary psychologists find a way to reconcile human diversity – whether it being cultural, linguistic, or behavioral – with the idea of a psychic unity of humankind, that is, the notion of a “universal human nature” (Buller 2005, 72).

Today, evolutionary psychologists propose various arguments for the universality of psychological mechanisms or adaptations. Among others, Cosmides and Tooby (1997) propose what David Buller dubs “the argument from *Gray’s Anatomy*” and “the argument from sexual recombination” (Buller 2005, 73). The former deduces the universality of “selection-designed psychological traits” from the universal character of “selection-designed morphological traits,” on the grounds of the fact that everything, from our bodies to our minds, has been drafted by selection (Buller 2005, 73). The latter, on the other hand, infers the universality of all complex adaptations, such as psychological adaptations, from the fact that the genetic basis of adaptation necessarily imposes “species universality” (Buller 2005, 424). Furthermore, informed by research in cultural anthropology, evolutionary psychologists reaffirm the intimate connection between the psychic unity idea and an antiracist attitude toward

the study of human behavior. As Tooby and Cosmides (1992, 38) explain “...models of a robust, universal human nature by their very character cannot participate in racist explanations of intergroup differences. (...) Human nature is everywhere the same.”

Contemporary Debate on the Idea of Psychic Unity

Contemporary claims on the existence of a psychic unity of humankind have not remained uncontested. Today, universalist theories about language, cognition, psychology, and culture face the criticisms of a number of linguists, cognitive scientists, evolutionary psychologists, as well as philosophers. Contrasting arguments about the possibility of delineating the universal traits of a supposed human nature fuel contemporary debates about the idea of psychic unity, while some universalist approaches are undergoing a massive reshaping following the emergence of new data which demonstrate the existence of considerable crosslinguistic and cross-cultural variation as well as the nonuniquely human character of some traits that were previously thought to be distinctive of our species (Everett 2013, 21).

Today, adherents of generative linguistics cautiously distinguish between a “faculty of language in the broad sense (FLB)” and a “faculty of language in the narrow sense (FLN)” (Hauser et al. 2002). On this view, whereas FLB can be found in humans and other species as well, the latter can be conceived as uniquely human (Hauser et al. 2002, 1578).

Linguistic typologists also use a more tempered language by understanding language universals as “tendencies,” rather than “strict universals” or “uncontroversial facts” (Evans and Levinson 2009, 429–431), i.e., as properties that are common to many languages and whose identification necessarily requires to be “non-aprioristic,” but based on the examination of “a sufficiently large and reasonably representative set of languages that have not influenced each other in recent times” (Haspelmath 2012, 91–99). Within linguistic typology, then language

diversity ceases to be a mere superficial appearance and becomes a fact with “long historico-cultural roots that explain the many divergences,” which should be accepted and studied as such (Evans and Levinson 2009, 432). Such diversity, as Evans and Levinson (2009, 431) notice, reveals the centrality of “cultural and technological adaptation in our species: language is a bio-cultural hybrid, a product of intensive gene-culture coevolution over perhaps the last 200,000 to 400,000 years.” In light of this, as language turns out to be not just a biological product, but also a cultural-historical artifact, language and its universal tendencies need to be studied from within “a coevolutionary model” (Evans and Levinson 2009, 446). In addition, according to scholars in linguistic typology, the acknowledgement of the importance of culture for the development of human language allows one to go beyond the threat of ethnocentrism and the limitations of nativism that appear intrinsic to the generativist approach to linguistic universals (cf. Haspelmath 2012, 99; Evans and Levinson 2009, 445).

According to Evans and Levinson (2009), the above arguments have fundamental implications for the universalist approach to cognitive research too. In their opinion, the increasing evidence of structural language differences should lead cognitive scientists to stop searching for cognitive universals in the wake of generative linguistics and to develop “a new approach to language and cognition that places diversity at center stage,” “a comparative psychology inside our own species in the central questions that drive cognitive science” (Evans and Levinson 2009, 429–432). Some cognitive scientists are already proposing such a comparative approach to cognitive research and point to the existence of cross-cultural variation to challenge nativist approaches to folk psychology and folk biology (Ravenscroft 2019).

Universalist arguments in evolutionary psychology too have not gone unopposed. David Buller (2005), Stephen Downes (2010), John Duprè (2001), David Hull (1986), and Tim Ingold (2006) have similarly argued that the evolutionary psychological notion of human nature is untenable as it conflicts with evolutionary biology and does not take human variation into consideration.

One for all, Buller (2005) puts forward five main critiques against such notion:

1. Both “the argument from sexual recombination” and “the argument from Gray’s Anatomy” that Cosmides and Tooby (1997) propose in support of the universality of psychological adaptations are unwarranted (424). According to Buller, whereas the former can be rejected on the grounds of the fact that “selection can, and frequently does, maintain polymorphism of complex adaptations within populations” (424), the latter appears unsustainable because it rests upon “a questionable analogy between anatomy and psychology,” among other things (425).
2. The notion of human nature relies on an arbitrary distinction between “normality” and “abnormality,” which finds no support in contemporary biological theories (428–438).
3. The idea of human nature is based upon an essentialist view of species, but Buller shows that species are individuals, rather than natural kinds, and hence there cannot be “species-specific psychological laws” that apply uniquely to human beings (439).
4. Buller shows that, contrary to what evolutionary psychologists hold, the existence of cultural universals does not necessarily corroborate the idea of a universal human nature consisting of psychological universals (471). This is because psychological universals are not the only possible mechanisms that lead to cultural universals. The latter could instead derive from a number of other processes (462–471). (In this regard, some of the classic examples of human universals – Jay Odenbaugh 2015 cites inbreeding avoidance and incest taboos, while Rafael Núñez 2017 refers to numerals – are demonstrably flawed: they are either too wide ranging to be uniquely human or too particular to represent universals of human nature (cf. Odenbaugh 2015, 9). Moreover, as Ingold 2006, Duprè 2001, and Núñez 2017 argue, many of such examples are fundamentally Western centric. In light of this, although the psychic unity idea has undoubtedly contributed to the affirmation of human

- equality against racist claims, such notion appears to have a fundamental “reverse ethical significance” (Job 2006), whereby it would back the West’s presumptions of superiority up by grounding human universals in Western principles and values (Ingold 2006, 262–279)).
5. For Buller, once we comprehend the true import of evolutionary theory, we will see that “our current adaptations” – whose roots evolutionary psychologists locate in the Pleistocene period – are “no more definitive of our ‘nature’ than past or future adaptations” (480) (cf. Downes 2010). In light of current evolutionary theory, it appears that our adaptations are “no more definitive of our ‘nature’ than nonuniversal adaptations and non-adaptations” (480).

Whereas Buller (2005), together with Hull (1986), Duprè (2001), Ingold (2006), and Odenbaugh (2015), remains skeptical about human nature, other scholars maintain that it is still possible to sensibly speak of human nature in biological terms (for an extensive review of some of the main arguments for and against the notion of human nature defended by evolutionary psychologists, see Downes (2018). Among others, Clark Barrett (2015) proposes to extend the evolutionary psychological notion of human nature to include human variation (reviewed in Downes 2018). Edouard Machery (2008), on the other hand, proposes a nomological notion of human nature, in opposition to an essentialist one. To Machery (2008, 322), Buller and Hull’s critiques to human nature invalidate only the essentialist notion of human nature, which has its roots in folk biology and which understands human nature as “the [distinctive] set of properties that are separately necessary and jointly sufficient for being human.” Machery (2008, 323; emphasis ours) thereby defends a nomological notion of human nature that interprets human nature as “the set of properties that humans *tend* to possess as a result of the evolution of their species.” According to Machery (2008, 328), such nomological notion, and not the essentialist one, corresponds to the idea of psychic unity espoused by evolutionary psychologists.

Both Barrett’s and Machery’s theories are not spared from criticism. Whereas Barrett’s view has been criticized for being a mere “big list of all the properties that humans have had and can have” (Downes 2018), Machery’s has been attacked for giving rise to a “far more permissive” notion of human nature than he intended, leaving us wondering whether, today, a concept of human nature is still at all useful (Lewens 2015, 78–79).

Conclusion

Over the centuries, scholars in various disciplines have contributed to refining the conceptual contours of the psychic unity idea onward and upward. In so doing, they have sometimes come to tie it with contrasting theories, such as relativist and universalist interpretations of human worldview formation. In spite of the diverse usages of the psychic unity concept, its advocates have generally agreed in regarding the existence of uniform cognitive capacities as a proof of human equality.

Contemporary accounts of human universals, whether they are cognitive, linguistic, psychological, or sociocultural, remain ideas defended by some and criticized by others in all fields, including philosophy, psychology, anthropology, and linguistics. Proponents newly back up the psychic unity idea and its inherent ethical dimension by pointing to a shared evolutionary history, similar genetic endowment, alike brain structures, and common sociocultural values. On the other hand, some scholars oppose such idea by citing the radicality of human variability, the threats of Western-centrism, the limitations of nativism, and the importance of considering gene/culture coevolution for understanding human evolutionary development.

Psychodynamic Foundations

Tommie Forslund¹ and Pehr Granqvist²

¹Uppsala University, Uppsala, Sweden

²Stockholm University, Stockholm, Sweden

Definition

Westen (1998) has defined psychodynamic theories with five postulates: (1) much of mental life is unconscious; (2) mental processes operate in parallel so that people can have conflicting feelings that motivate them in opposing ways; (3) stable personality patterns begin to form in childhood, and childhood experiences play an important role

in the developing personality, particularly in shaping social relationships; (4) mental representations of the self, others, and relationships guide people's interactions with others and influence psychological symptomatology; and (5) personality development involves learning to regulate sexual and aggressive feelings but also the move from an immature, socially dependent state to a mature, interdependent one. According to this definition, attachment theory is a psychodynamic theory. However, Bowlby explicitly demarcated his attachment theory from the drive principles.

Introduction

John Bowlby, a psychoanalyst and child psychiatrist, was interested in the close and continuous relationships – attachments – that children develop to their caregivers, the importance of children's actual experiences with their caregivers, and the potentially negative effects of early separations. Bowlby was dissatisfied with parts of the psychoanalytic metatheory, which he deemed unscientific. In particular, he could not accept the secondary drive theories that explained attachment as a secondary result of psychical energies and drives. Bowlby, who sought to reform psychoanalysis and provide a scientific theory for attachment, came to draw on evolutionary theory and ethology as well as cybernetics and cognitive psychology. The present discussion outlines the similarities and differences between attachment theory and psychoanalysis.

Psychodynamic Roots to Attachment Theory

Bowlby became interested in psychoanalysis while studying medicine at Cambridge University, and after becoming a psychoanalyst he remained a member of the British Psychoanalytical Association until his death. Bowlby thus had his roots in psychoanalysis. He also acknowledged Sigmund Freud for some of his contributions and accepted parts of the psychoanalytical metatheory; "Throughout this inquiry my frame of reference

has been that of psychoanalysis... the central concepts of my schema – object relations, separation anxiety, mourning, defence, trauma, sensitive periods in early life – are the stock-in-trade in psychoanalytical thinking” (Bowlby 1997, 1982, p. xv). Indeed, Bowlby argues at length in the first part of attachment and loss that many of his ideas are in accord with Freud’s, although formulated in modern scientific terms. Bowlby also argued that Freud – who himself reformulated important parts of psychoanalysis, treated its claims as preliminary, and sought a scientific basis for psychoanalysis – would likely have welcomed Bowlby’s ideas and scientific scrutiny.

Bowlby’s relationship with the psychoanalytic school of his time was, however, conflicted, as he viewed parts of the metatheory as unscientific. When Bowlby became a psychiatrist the British Psychoanalytical Association was territorial and ravaged with conflict. There were two main psychoanalytical schools, one revolving around Anna Freud who adhered to Sigmund Freud’s ideas and another revolving around Melanie Klein who had her own version of psychoanalysis. Despite their differences these schools nonetheless largely agreed on the basic tenets of the metatheory. In discussing psychoanalysis in relation to attachment theory, Bowlby used Rapaport and Gill’s (1959) description of the psychoanalytical metatheory as involving postulates regarding five principles: the dynamic (psychological forces), the economic (psychological energy), the structural (psychological structures), the genetic (psychological origin), and the adaptive (relationship to the environment).

Specifically, Bowlby contested the dynamic and economic, which in terms of a “psychical energy model” postulated that humans are endowed with a closed system containing distinct kinds of psychical energies that independently build up and need discharge in order to obtain homeostasis. These theories thus put a heavy emphasis on children’s drives (i.e., psychical energies), as primary motivational systems affecting psychological development through channeling of psychical energy. Along these lines it was argued that children’s attachments were a secondary result of psychical energies and feeding.

Bowlby called such theories “secondary drive theories,” and more sarcastically, “the cupboard theories of love.” Bowlby argued against the existence of any special type of energy beyond the energy of physics, deeming psychical energies as redundant. Bowlby, who thought that actual experiences with caregivers are important, sought to reform the psychoanalytic theory, the claims of which he argued should be aligned with scientific knowledge from other disciplines.

An Alternative Motivational Theory

Bowlby was part of a “third-wave” psychoanalytic school, often referred to as the British school of objects relations, and was particularly influenced by Donald Winnicott, who shared his view that children are sensitive to social interactions and in need of healthy interactions to develop well (see ► [“John Bowlby: Pioneer of Attachment Theory”](#)). However, Bowlby thought that the other object relation theorists lacked an alternative to the instincts/drives proposed by Freud. Bowlby viewed attachment as a primary instinct/motivation and argued – drawing on evolutionary theory and ethology (i.e., imprinting and attachment behaviors in rhesus monkeys), and observations of human children’s behaviors – that the attachment system is a behavioral control system that has been retained because it served an adaptive function in our ancestral environments (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)). Specifically, Bowlby proposed that the function of the attachment system is seeking and maintaining proximity to caregivers as it has served an adaptive function for survival by protecting offspring from predators and other natural dangers (see ► [“Infant Survival”](#)). Another difference between attachment theory and psychoanalysis is thus the usage of animal data and observations of how other species respond to similar situations, regarding presence or absence of caregiver(s).

The attachment behavioral system, Bowlby argued, is open to and interacting with the environment, with attachment behaviors triggered and terminated by internal and/or external information

(e.g., changes in the environment). Bowlby argued that the better our understanding of the causal factors influencing the workings of behavior systems “the less useful the concept of drive becomes” (p. 136). With the words of Bowlby: “Termination is due not to a running down of some clockwork mechanism or to the running out of some psychical energy but to a specific signal” (Bowlby 1997, 1982, p. 94). Regarding the concept of homeostasis, Bowlby argued for a behavioral homeostasis as opposed to one based on psychical energies, and he attributed variations in the intensity and duration of attachment behaviors to variations in the activating conditions and the developmental state of the behavioral system (see ► [“Offspring–Parent Attachment”](#)).

An Alternative Method

Bowlby also sought to make the psychoanalytic theory more scientific by formulation of testable claims and usage of empirical hypothesis-driven methods for testing these claims; “There can be no doubt that if psychoanalysis is to attain full status as one of the behavioral sciences, it must add to its traditional method the tried methods of the natural sciences” (Bowlby 1997, 1982, p. 9). Psychoanalytic theory regarding children’s development was at the time largely based on reconstruction of case reports obtained from adults, which were debated in seminars. Direct observations of children were rare and theories about children’s development were thus largely based on hypotheses derived from an end product and backwards by means of historical reconstruction; “the events and processes inferred belong to a phase of life that is already passed” (Bowlby 1997, 1982, p. 3). Bowlby also argued that it was dangerous to overrate the data obtained in analytical sessions as the data (i.e., “free associations”) was likely restricted by the subject and selectively interpreted depending on the analyst’s theories.

In contrast, Bowlby advocated the usage of empirical methods, most notably careful observations of children in real-life situations, as he argued that young children’s behaviors are less restricted and thus more likely to reflect their

mental states. These observations, he proposed, should be conducted in prospective designs for forward extrapolation, wherein children’s development and the possible effects of presumed pathogens are followed over time. In Bowlby’s case, the presumed pathogen was early separations (see ► [“John Bowlby: Pioneer of Attachment Theory”](#)).

Finally, attachment theory has a comparatively specific topical focus (i.e., on attachment) and may be understood as a “mid-level” psychological theory. In comparison, the topical focus of psychoanalysis is much broader.

Similarities Between Attachment Theory and Psychoanalysis

Bowlby accepted parts of psychoanalysis, although with some modifications (the adaptive, the structural, and the genetic). For example, Bowlby noted that many of Freud’s early ideas regarding factors causative of neurosis centered on the notion of trauma, and Bowlby perceived early separations and severely dysfunctional caregiving as potential traumatic agents. Bowlby was also, as Freud, convinced that we have psychological defenses that protect us against anxiety, but Bowlby formulated these defenses in terms of information processing and memory functions, following Dixon (1971) and Norman (1976). Instead of psychoanalytical defenses such as projection and denial, Bowlby argued for the development of cognitive-affective strategies that deal with threatening information regarding attachment (see Fonagy 1999). Specifically, Bowlby argued for two mutually dependent strategies: defensive exclusion and shifting of attention. Bowlby based defensive exclusion on the fact that organisms exclude irrelevant information to liberate processing capacity, and argued that the process of “defensive” exclusion is based on such processes, with the goal of shielding the organism from thoughts and feelings that would cause overwhelming anxiety and suffering as well as maladaptive behaviors. Shifting of attention is intimately connected to defensive exclusion and is, for example, seen when an individual shifts his/her attention away from attachment and

instead focuses on other aspects of a situation or on other persons than the attachment figure (e.g., Main 1991).

The development of psychological defenses was thought by Bowlby (e.g., 1973) to stem from early interactions with caregivers, with memories of these interactions organized as (implicit) internal working models (IWMs) of self and others. Insensitive caregiving was assumed to lead to the construction of incoherent (or multiple) IWMs whereby the later-emerging explicit layer of IWMs differ from the implicit layer. Thus, when asked about a caregiver, an adult may say that the caregiver was loving and sensitive (explicit/semantic processing) but fail to provide consonant examples (implicit/episodic processing). Bowlby argued that these defenses may be adaptive in the short run but maladaptive in the long run, as the attachment system may become deactivated or hyper-activated. Bowlby was careful to point out that the IWMs were “none other than the internal worlds of psychoanalysis seen in a new perspective” (Bowlby 1997, 1982, p. 82) and regarded psychopathology (cf. neurosis) as due to inadequate or inaccurate IWMs.

Attachment Theory and Psychoanalysis Today

As reviewed by Fonagy et al. (2008), there has been a rapprochement between attachment theory and psychoanalysis. This has several reasons. First, it has been increasingly acknowledged that the perspectives share common foundations (as Bowlby argued from the start), such as the central role given to the first object(s) (i.e., caregivers), the importance of nonconscious mental states, and the notion of psychological defenses. The rapprochement also stems from changes within the psychoanalytical field. Importantly, object relations theories (the psychoanalytical school to which Bowlby belonged) has become dominant in psychoanalysis. These theories, which are relational, share an assumption that development of subjectivity is interpersonal (cf. intersubjectivity), and hence emphasize early experiences in close relationships. Attachment

theory has been important and influential for several such theories, pertaining to both the theoretical postulates and the empirical approach advocated by attachment theorists. Indeed, psychoanalysts have increasingly accepted the need for systematic empirical examination, perhaps in part to counteract frequent charges of “pseudoscience.” The empirical approach advocated by Bowlby and other attachment theorists, and the empirical findings spurred by attachment theory, are now seen as an empirical foundation of psychoanalysis (Fonagy et al. 2008). The rapprochement was also facilitated by the linguistically based “representational” methods for examining attachment in older children, adolescents, and adults that were developed based on the concept of IWMs and their workings (Main et al. 1985). These methods ultimately opened the door to a closer examination of attachment in relation to psychoanalytical concepts, as well as to clinical usages of attachment theory with adults (Fonagy et al. 2008; Slade 1999).

Conclusion

Although Bowlby had his roots in psychoanalysis, and accepted some parts of the metatheory, there are important differences between attachment theory and psychoanalysis. Theoretically, Bowlby contested the psychical energy model which argued that children’s attachments were the secondary results of psychical energies and feeding. Bowlby instead argued that humans are endowed with a behavioral attachment control system that is activated and terminated by external and internal signals, and which has developed as it has had adaptive advantages in terms of survival in our evolutionary history. Methodologically, Bowlby also argued for scientifically formulated and testable psychological theories and usage of prospective methodology, naturalistic observations, and animal data. There has, however, been a rapprochement between attachment theory and psychoanalysis, in line with Bowlby’s quest to modernize psychoanalysis and give it an empirical foundation, as modern psychoanalytical approaches have often adopted both attachment theory and the empirical approach that Bowlby argued for.

Definitions

Psychological, in this context, refers to patterns of thought and behavior across both individual and species-typical levels of description.

Determinism refers to the necessary and sufficient conditions of prior ascriptions of such patterns to the extent that they can provide causal indicators. The precise nature of what this means will be explored in more detail below.

Introduction

“Probability is the most important concept in modern science, especially as nobody has the slightest notion what it means,” so said Bertrand Russell, in 1929 (cited in Bell 1945). Chance and necessity, or, to put it differently, probability and determinism, lie at the heart of science. However, thinking about determinism is harder than it might initially appear, because thinking about probability is harder than is commonly supposed. Because scientists, naturally enough, draw on the most foundational science – namely, physics – for clarity and inspiration, it is very important to be clear about what is, and is not, implied by this, our most basic and predictively powerful science, if one wishes to understand what *determinism* could possibly mean at the levels that the behavioral sciences operate.

What is it to say that *x* caused *y*, or, perhaps, that the measurement of event *y*, was fully determined by the occurrence of cause *x*? Wilfred Sellars (1963) made a famous, and useful, distinction between the *manifest* and *scientific* images of the world. The manifest image is, essentially, the conception of things as it developed in human evolution, supplemented and clarified in various ways so as to bring it into line with modern knowledge. It thus contains such things as colors, living beings, and human relationships, together with more recent discoveries such as parliamentary democracy and fiat money. The scientific image is the modern scientific conception of the world. It thus contains such things as atoms, quarks, and the four fundamental forces.

In which of these two images – scientific or manifest – do *determinism*, and the attendant concept of *free will*, belong? Can the separate pictures be reconciled? The issue is pressing for psychologists, because elements of the scientific image – particularly those driven by particular understandings of physics – keep bleeding through from the scientific into the manifest image, allegedly rendering some concepts obsolete. There are many technical ways in which this can occur, but, broadly, these intrusions come in two varieties. They both derive from particular conceptions of the most basic and predictively powerful physical theory that humans have achieved – namely, quantum mechanics.

On the one hand, those (sometimes of a mystical bent) who think that quantum mechanics reveals a previously hidden universe of true randomness can hold out for a version of free will which owes a lot to the ancient concept of the Lucretian swerve. On this view, some events happen for (literally) no reason whatsoever, and, so the thought goes, if this sort of thing is happening in human brains – in microtubules perhaps – then humans are freed from the causal prison that the rest of the universe is trapped in.

It is not clear, however, how things happening for no reason whatsoever could lead to free choice as it features in the manifest image. In the manifest image, freedom isn't simply a pleasant feeling generated by reflections along the lines of “Hey! I'm free! So much nicer than being a robot.” Rather, free will is a concept intimately linked to the moral, legal, and social norms governing relations between individuals and the organization of society as a whole (see, e.g., Dennett 2004). It is also intimately connected to both psychological and commonsense understandings of humans as agents with intentions. To work in this way, as morally and socially foundational, choices have to meaningfully proceed from relevant personal features such as our characters and wishes, thus preserving agency. There are, in other words, reasons for our choices.

On the other hand, those who think that quantum mechanics can be interpreted in deterministic ways have been known to call for the abandonment of concepts of human free will entirely

and to (for reasons that are also not entirely clear) go on to call for the complete overhaul (or abandonment) of moral and legal systems in the light of this.

Psychology Studies That Appear to Undermine Human Agency, via Deterministic Forces

Often, this view of hard determinism, incompatible with free will, is buttressed by findings from social and neurocognitive sciences that appear to show that our human sense of free choice is demonstrably illusory. Examples abound, but the particularly popular go-to studies are of four kinds.

First are those where a person's moral sense does not prevent them from performing apparent atrocities under orders (e.g., Milgram 1963). Second are those where the sensation of an (arbitrary) choice is preceded by unconscious but measurable neural activation (e.g., Libet 1993). Then, there are experimental demonstrations of illusions of causal efficacy, when suitably pranked by a researcher (e.g., Wegner 2002). Finally, there is research into *ex post facto* rationalization – often taken to imply that so-called reason is a human conceit with no causal power.

These studies are all interesting and certainly help us understand, in sometimes excruciating and embarrassing (to a particular view of the human species) detail, the role of environmental forces, and *ex post facto* rationalizations, in human affairs. But it needs to be understood that such studies are interesting precisely *because* not all behavioral events are like them. It is because we usually, or in the case of rationality at least *sometimes*, behave in ways that make enactivist sense in our environment – sometimes emerging from a process of reasoning and education, sometimes from processes of training, that we can typically stand over and meaningfully own our actions. A brief survey of why this is, in each type of case, might be useful at this point.

Social Pressure

In the case of the social pressure studies – Milgram (1963) being the most well-known

example – it is a salutary lesson to realize that many of us can be led to do wicked things. Surprisingly little social pressure can be brought to bear to get people to carry out apparent atrocities (such as shocking an innocent stranger) against their consciences and against prior psychological predictions of the incidence of psychopathy in the population. The occasional attempts at debunking the validity of such studies (usually in terms of ecological validity or faux-naïveté of participants) are not our focus here.

History is, alas, replete with people who did not know what they were capable of, until it was too late, and perform far worse atrocities than in any social science lab experiment. And, history is neither ecologically invalid nor filled with participants only pretending to play along. The point is that not everyone succumbs to social pressure. Milgram reports (too little, alas) on some who refused to take part or who bailed early on the studies. Indeed, there is evidence that even learning about such studies makes people consider cases of obedience more thoroughly in the future. The fact that many of us are not as morally strong as our self-image proclaims is not a finding that we needed social psychology to teach us, although Milgram-style experiments should put paid to any complacent assumptions about what sorts (or nations) of people resist social pressure.

"It Was Not Me, It Was My Brain"

Libet (1985) was the first to show, via EEG, that a spreading neural activation pattern – readiness potentials – in a small brain region preceded the conscious experience of an arbitrary choice. Later studies, using fMRI technology, confirm that something like a prediction can be made to such choices, some seconds in advance of conscious experience (Soon et al. 2013). Some have concluded, from these sorts of findings, that consciousness is a mere epiphenomenon with no causal efficacy.

It is worth pointing out that some of the rhetorical work eroding free will done by such studies relies on not mentioning that these so-called predictions take hours of processing on the part of the brain scanners. This is not mere detail – a lot

of the force of such experiments in undermining a sense of agency comes from not drawing attention to such salient features.

More importantly, it is much less clear if such a dizzying loss of agency, which some report, would be felt if a decision actually mattered to the decider and could be shown to originate in a variety of coordinated brain states. As Marvin Minsky (1996) cheerfully puts it, “When someone says, ‘I just thought of something’, what they usually mean is that they just stopped thinking about that thing.” For instance, if someone points to my voting decision, as a target behavior outside of my conscious will, and traces that eventual decision to, variously, a part of my brain that processes empathy, and another part that processes arguments, another that...and so on...it is less clear that the fact of my action resulting “just from my brain” should trouble me in the slightest, in terms of agency. Where else could anyone want such a decision to issue from?

The fact that so much of the processing is unconscious should not worry anyone more than when a crossword answer just “pops” into the solver’s head after putting it aside for a while. They still solved the puzzle, in any meaningful sense. Indeed, many of the acts that are the most agentic in this sense are ones where we have trained ourselves so that our responses occur somewhat in advance of our conscious will. Emergency braking is a good example. We deliberately (and consciously) train ourselves to react without deliberation and no one seriously believes this undermines our agency.

The Illusion of Conscious Will?

Wegner produced some of the most famous of these studies of false control, where someone’s sense that an event is being controlled is pranked by the experimenter. Everyday instances of this – such as the ideomotor response that causes a pendulum swing or a Ouija board pointer to move – are familiar enough and raise the interesting point that the mere feeling (or absence of feeling) of conscious willing is neither necessary nor sufficient for causal ascription. But the existence of such phenomena are no more a general challenge to an everyday sense of control, than are optical

illusions to our sense of a generally informationally useful (which is not to say naively realist) sense of perception. Ideomotor automaticity, or the unconscious betrayal of our desires without conscious intention, is unsettling precisely because most of the time we have as much control as we need for everyday purposes. It is not clear what is to be gained by attempting to collapse complex cases into simple ones and then reading too much into the simple cases.

Well-controlled lab experiments (e.g., McConkie and Rayner 1975) that measure responses to stimuli presented with full conscious awareness, partial awareness, and absence of awareness show measurable differences in behavior. Thus, it is empirically inescapable that consciousness is no mere epiphenomenon. It is also plausible that it is not an all or nothing event but admits of degrees. Many, although by no means all, researchers are converging on a view that consciousness roughly corresponds to functionally important global access (e.g., Baars 2007).

Reasons and Causes

What is the causal efficacy of human reason? We will briefly consider two extreme versions before suggesting that a middle ground is sustainable and, furthermore, the sort of trait that could have reasonably evolved.

“One wants to be what tradition has it that Eve was when she bit the apple. Perfectly free to do otherwise. So perfectly free, in fact, that even God couldn’t tell which way she’d jump” (Fodor 2003). This is one extreme, namely, contra-causal free will that is somehow governed by reason. Such an extreme version seems to require a Cartesian separation of mind and body with all the attendant problems that has. That is one position on a continuum.

At the other extreme stands a variety of insights, from Freud onward, that a great deal of what humans produce as reason are, in fact, ex post facto *rationalizations*. That this is the case cannot be reasonably be in dispute. However, some might go further and claim that *all* reasons are of this kind and that reason acts merely as an advocate. In response to this, it should be pointed

out that this is, itself, only ever offered as a reasoned argument, intended to produce consequences in its listeners. If this, extreme, version of the rationalization argument were to be taken to its logical conclusion, then it would have the odd consequence that reasoned argument could only convince those outside of one's head, never oneself.

It is not just the circularity that means that this extreme position cannot be true. The logic here is similar to the frequency-dependent selection Umwelt that can be the only fertile ground for lying. If everyone lies, all the time, then lies could never be effective. It is only against a background of typical truth-telling that lies can function as manipulations. Similarly, if reason were only a manipulator and never had any independent force (such as appealing to checkable evidence), then it could not function in the way claimed. It is precisely because reason, at least sometimes, has independent checkability that it can have causal efficacy on others and on oneself.

Quantum Mechanics and Determinism

We noted above that our enlightened moral and legal concepts depend on personal qualities which are not generally associated with unpredictability. If anything, it is the other way round: for instance, a trustworthy person is someone who reliably delivers on her promises. So quantum indeterminism as such has no obvious bearing on the question. However, quantum mechanics is potentially relevant in other ways.

Bargh and Earp (2009) characterize the traditional concept of free will in a carefully written passage which is worth quoting in full:

Free will may be defined as an agent's ability to act on the world by its own volition, independently of purely physical (as opposed to metaphysical) causes and prior states of the world. The folk notion of free will is laden with the concept of a soul, a nonphysical, unfettered, internal source of choice-making—in other words, an uncaused causer. “The soul” may have gone out of fashion, and “the mind” taken over many of its functions and connotations, but the intuitive notion of free will has stayed much the same: there is something inside each of us that allows us to make “real” choices, choices that even

an omnipotent being, one who knew every environmental influence, and every physical fact leading up to the choice-making event, could not foretell with perfect confidence and accuracy.

Instead of complete indeterminism, the definition merely specifies that the agent's actions cannot be predicted “with perfect confidence and accuracy” – which is a much weaker requirement and one fully consistent with the concept of freedom as it features in the manifest image (consistent, in particular, with the idea that the trustworthy person, who has never let anyone down, nevertheless acts freely). The weakening of the indeterministic element is balanced by the introduction of the concepts of autonomy and spontaneity, i.e., the ability to generate choices internally, in a way which is partially (it need not be completely) independent of both the environment (autonomy) and the previous history of the individual concerned (spontaneity). From the standpoint of classical (i.e., pre-quantum) physics, this idea may seem highly implausible. But how does it seem when viewed from the standpoint of quantum mechanics?

Quantum mechanics is an extremely well-tested theory which underpins a large part of modern technology. On one level it is therefore hard to doubt. At the same time, the question, as to what the theory is actually telling us about nature, continues to be highly controversial. The reason is that while the theory makes clear and unambiguous statements about what we can expect to *observe* in a given situation (which is why we are able to test it and apply it to practical, technological problems), it is much more enigmatic about what is going on when we are *not* observing a system.

Classical physics purported to give a picture of the universe as a whole, *sub specie aeternitatis*, rather as God might be imagined to see it looking down from above: A tapestry with each particle position, and each field value, precisely specified at every moment of time. To someone attached to this picture, the observer dependence of standard quantum mechanics is deeply unsatisfactory. There have consequently been numerous attempts to fill in the gaps and construct a picture which agrees with quantum mechanics so far as the

experimental predictions are concerned while at the same time giving a description of the universe as a whole, including those bits which are not being observed. Pictures of this kind are called ontological interpretations of quantum mechanics. They include the well-known examples of Bohmian mechanics (Bohm and Hiley 1993) and the Many-Worlds Interpretation (Saunders et al. 2010). Related to this are collapse models, which make different empirical predictions from conventional quantum mechanics and which therefore, unlike ontological interpretations, are in principle empirically verifiable/falsifiable.

It may be questioned, however, whether the classical ambition is as reasonable, or even as desirable, as it may superficially seem. After all, there can be no doubt that our actual cognitive situation is that of agents embedded *in* the reality we seek to describe. In ordinary life, we are accustomed to the fact that we can only see an object from this or that particular perspective and that if we pay attention, we become aware of such details as the nose between our eyes or the spectacles through which we are looking. It may be thought that the observer dependence of quantum mechanical statements is similar to this. There accordingly exist a number of interpretations, such as the Copenhagen Interpretation (Faye 2019), in which the observer dependence of quantum mechanics, rather than being seen as a vice, is embraced as a positive virtue.

A detailed analysis of the interpretation problem would be far beyond the scope of this entry. Our aim here is simply to make a few points about the situation, as it bears on the question of psychological determinism.

The two schools of thought just identified are more-or-less evenly balanced. Schlosshauer, Kofler, and Zeilinger (2013) polled the attendees at a conference on their foundational beliefs. It might surprise non-specialists to learn that there was a roughly even split between those who did and those who did not believe that physical objects have well-defined properties prior to and independent of measurement. Related to this, a clear majority appeared to believe that an observer is *not* a complex quantum system. Of course,

science is not democratic, and physicists are as capable of error as anyone else.

It is likely that a similar poll conducted in the year 1900 would have revealed that a majority believed the Newtonian theory of gravity to be the last word on the subject. But, what these considerations do clearly reveal is the existence of some significant divergences between the actual position in physics and the position as many behavioral scientists believe it to be. In particular, those behavioral scientists who think that a human agent is a physical system like any other and therefore cannot exhibit the two properties of autonomy and spontaneity described above are basing themselves on something other than the consensus among physicists.

Dropping the idea that physics should adopt an imaginary position outside the physical fray and replacing it with the idea that physics should adopt the viewpoint of the agent herself, fully immersed in that fray, means that one is assigning some kind of distinguished position to the agent (not necessarily a distinguished *physical* position, but certainly a distinguished *conceptual* position). This has the interesting effect of undercutting all the usual arguments against free will. There are two interpretations which are particularly noteworthy in this regard, in that free will plays a central role: QBism (Fuchs 2017) and Stapp's (2011).

QBism is relevant to this issue for two other reasons. As we noted at the beginning, the free will question arises from a collision between the manifest image, where the concept of free will is of fundamental importance, and the scientific image, where the concept seems much more questionable. It is not the only such collision, another example being the problem of consciousness. The occurrence of these collisions is closely related to reductionism: One attempts to reduce all the properties of the human organism to neural firings and the like and then finds oneself left with a residue of phenomena like free will or consciousness which are certainly hard and arguably impossible to satisfactorily reduce. Fuchs (2010, 2017) has proposed, as an alternative to reductionism, an approach which might be called additivism: The idea being that, instead of trying to reduce old conceptions to new ones (as with

reductionism), one regards the new conceptions as *additions* to existing knowledge.

The situation might be compared with that of someone who has purchased a charming old farm and wants to introduce some new technology. The cheap and easy solution would be to surround the existing buildings with a collection of prefabricated sheds, thrown up any-old-how, without regard for aesthetics. But a more satisfactory solution, albeit one requiring a much greater input of time and effort, might be to try integrating the old with the new. Similarly here. Perhaps, we have been too ready to slam down the scientific image *alongside* the manifest one, as a completely independent structure. Perhaps, with more effort we could have melded the two together, to form a seamless whole.

The other reason QBism is relevant to this issue has to do with modes of inference. Determinists think of causal relationships as physically existent entities. However, as Hume (1978) noted long ago, this notion is questionable. A photograph of a murder will show the smoking gun and the victim lying on the ground, but it will not show the causal relationship between them. Of course, one is free to postulate that the cause, although it happens, like a ghost, not to reflect visible light, is still something that exists physically, out there in the world. But one is equally free to postulate that it is unphysical. Few people are tempted to think of logical connectives like “and” or “implies” as the names of actual entities. It is possible to think of causes in a way similar to this, as logical constructs playing an important role in our thinking about the world, without being a physical part of the world.

Conclusion

Similar considerations as these apply to probabilities. It is possible to adopt a frequentist or propensity interpretation, according to which a probability is a physical entity. But, it seems to many, the present authors included, that it is more reasonable to think of them in Bayesian terms, as logical constructs (Appleby 2005). This is the approach taken in QBism, which is thus able to

give a unified account of determinism and indeterminism alike. From this point of view, the only difference between a deterministic theory, like Newtonian mechanics, and an indeterministic one, like quantum mechanics, is that in the former one typically has, given sufficient control over the experimental conditions, a much higher degree of confidence in experimental outcomes.

It thus appears that one possible way through the conceptual difficulties in quantum mechanics is precisely the same as that which a growing body of mathematically minded behavioral scientists are advocating to explain causal determination in their field of research – namely, Bayesian reasoning.

Psychological Evidence for Human Sperm Competition

Tara DeLecce

Synonyms

Anti-cuckoldry adaptations; Men's mating psychology

Definition

Humans have experienced sperm competition in their mating history, and men have evolved both physiological and psychological adaptations to prevent it, with the psychological ones focused on facilitating behavior toward achieving this goal.

Introduction

Sperm competition, in which sperm from more than one male are present simultaneously in a female's reproductive tract and therefore have to compete to fertilize an egg (Parker 1970), has been a recurring feature of humans' evolutionary past (Shackelford et al. 2015). Evolved psychological adaptations to avoid sperm competition are exhibited by men so that they do not suffer the costs associated with it (Shackelford et al. 2002). Specifically, as humans tend to form socially monogamous bonds, when females mate with another male other than her regular partner, the possibility arises that she may conceive offspring with the extra-pair male and trick her partner into raising genetically unrelated children (Shackelford et al. 2015). Because this can greatly reduce men's reproductive success, men's mating psychology is sensitive to female infidelity and ways of preventing or even correcting it.

Copulatory Desire Adjustment

When men are at greater sperm competition risk, it is argued that they inseminate more sperm when copulating with their partner than when they are at lesser risk (Baker and Bellis 1993). However, this is a physiological adaptation, and it could not successfully be executed without psychological adaptations to facilitate the appropriate behavioral and/or physiological response to sperm competition. Shackelford et al. (2002) proposed that, generally speaking, men would have increased copulatory desire toward their partner when they perceived a greater sperm competition risk to facilitate actual copulatory behavior.

More specifically, they found that for men who spend more time apart from their partner since the couple's most recent copulation rate their partner as more attractive, report that other men find their partner more attractive, report greater interest in copulating with their partner, and report that their partner is more interested in copulating with them. The authors thought this was due to the greater time spent apart since the couple's last copulation as time apart could be an opportunity for men's partners to copulate with other men. It is important to note that this finding was independent of total time elapsed since the couple's last copulation, which refutes the alternative explanation that men are just getting increasingly more sexually frustrated as time goes on. However, time spent apart since the couple's last copulation is not the only cue of sperm competition risk, and men are sensitive to multiple cues. This increased copulatory desire is also activated by the presence of potential rival males. Pham and Shackelford (2013) found that men whose regular partner spends more relative to less time with male friends (i.e., potential sexual rivals) express greater interest in copulating with her. Yet another cue is female attractiveness (as attractive women draw more male attention), as men who perceive their partner as particularly attractive report more desire and actual performance of in-pair copulations with her if she has a large number of male friends and coworkers (Pham et al. 2014).

Distress upon Sexual Refusal and Sexual Coercion

Another component of psychological adaptations to sperm competition is that men feel distress upon their partner's refusal of a request for copulation if they perceive themselves to be at high sperm competition risk (Pham and Shackelford 2013; Shackelford et al. 2002). When men's and women's sexual strategies are at odds with one another (known as intersexual conflict), male sexual coercion is more likely (Shackelford and Goetz 2012). Specifically, women are more interested in mating with an extra-pair male during the fertile phase of their ovulatory cycle if their

regular partner is relatively unattractive, and they are also more likely to postpone copulation with their regular partner if they actually follow through with such desires (theoretically to give the rival male an advantage in sperm competition; Shackelford et al. 2015). This conflicts with the in-pair man's reproductive goal of avoiding sperm competition, and under these circumstances, men are more likely to feel distress upon sexual refusal and subsequently coerce their partner into copulation to put their sperm into competition with that of the rival male (Shackelford and Goetz 2012).

Consistent with this reasoning, men who are at greater objective sperm competition risk are more likely to engage in sexual coercion, but only if they perceive a high likelihood that their regular partner engaged in an extra-pair copulation (McKibbin et al. 2011). Perhaps this is why men who report sexually coercing their partner are also more suspicious of her committing sexual infidelity and why women who report a greater interest in pursuing extra-pair copulations claim their partner is more sexually coercive (Goetz and Shackelford 2009).

Sexual Stimuli Preferences

Because increased and prolonged sexual arousal before ejaculation is associated with better sperm quality (Pound 2002), it is likely that men's increased sexual arousal to stimuli involving sperm competition is another psychological adaptation to increase reproductive success. Accordingly, investigations of pornographic videos and websites reveal that pornography featuring two men interacting with one woman (a scenario indicating sperm competition) is more popular than pornography featuring two women interacting with one man (a situation lacking sperm competition; Pound 2002). This finding also matches up with men's self-reported preferences (Pound 2002).

An alternative explanation unrelated to sperm competition for this preference was proposed, stating that men were reporting greater arousal from this type of pornography due to the presence of multiple and simultaneous sexual acts (e.g.,

vaginal sex, oral sex). To rule out this possibility of hypersexuality, pornography including multiple males and multiple females interacting were also included (as these should be the most super-stimulating), and the preference for the two-men and one-woman scenario remained (Pound 2002).

Conclusion

Sperm competition has had considerable influence not only on men's physiology but also on their mating psychology. It is related to men's sustained copulatory interest in a regular partner and what types of erotic stimuli they find the most arousing. Sperm competition even plays a role in morally controversial behavior, such as sexual coercion. All of these psychological adaptations work together with physiological ones to effectively reduce the chances of men's regular partner conceiving with a rival male and thus optimizing the chances of reproductive success.

Definition

Psychology is the scientific study of the mind and its functions, including emotions and behaviors. The Trolley Problem has been used to study morality, particularly moral behavior, within psychology.

Introduction

The Trolley Problem is a moral dilemma first used by philosophers and then adopted by psychologists to examine moral thinking (Cathcart 2013). The original problem was created by Philippa Foot and involved deciding whether or not to switch a trolley that was speeding toward five people to a new track with only one person on it (i.e., whether you should sacrifice one life to save five; Foot 1967). Several variations of the Trolley Problem now exist, such as the Fat Man variant where the individual must decide whether or not to push a fat man on the tracks to save five people (Cathcart 2013).

The Psychology Behind the Trolley Problem

Psychologists have used the Trolley Problem and its variants to study the individual differences and other factors that influence moral behavior. For example, people are more likely to sacrifice one

person to save five if it involves less contact (i.e., pulling a lever versus pushing a person; Greene 2013; Singer 2005) and if they possess certain dark personality traits (Greene 2013). The characteristics of the would-be victim also influence moral decision-making, whereby younger, more closely related people, and current/potential romantic partners are less likely to be sacrificed to save the five people on the track (Bleske-Rechek et al. 2010). That people prioritize themselves, genetic relatives, younger individuals, and current or potential mates over others suggests that human moral thinking is rooted in our evolutionary history (e.g., reproductive drives; see Bleske-Rechek et al. 2010). Other evidence suggests that culture impacts moral decision-making, with people from collectivistic cultures being less likely to sacrifice one to save five than people from more individualistic cultures (Gold et al. 2014).

Conclusion

The Trolley Problem and its variants, although originally developed in the field of Philosophy, is a useful scenario for research into human behavior and can be used to investigate the psychology of moral decision-making. Moreover, these moral dilemmas can be used to test evolutionary theories surrounding aspects of human social behavior.

Psychology of Reciprocal Altruism

Jeffrey R. Stevens and Juan F. Duque
University of Nebraska-Lincoln, Lincoln, NE,
USA

Synonyms

[Reciprocity](#)

Definition

Different forms of reciprocal altruism – taking turns offering altruistic help – require different psychological building blocks.

Introduction

A pair of pied flycatchers busily snatch insects to bring back to their nest and feed to their young. Suddenly, an owl appears close to the nest, posing

a serious predation threat to their offspring. The pair fly straight to the owl, shrieking and dive bombing it to chase it away. A nearby pair of flycatchers detects the ruckus and also arrives to attack the predator. Another nearby pair, however, fails to help. An hour later, two owls appear, one at each of the neighboring nests. What should the original pair do? Krams et al. (2008) conducted this experiment and found that, out of 32 pairs of flycatchers, 2 stayed at the nest, 30 attacked the owl near the pair who helped them previously, and none attacked the owl near the pair who did not help them before. This willingness to pay a cost to cooperate or help another who has helped you before is called *reciprocal altruism* or *reciprocity*.

Natural selection favors genes that benefit the individual relative to others in the population. At first glance, it is unclear how altruistic cooperation could evolve since it benefits another individual at a cost to oneself. Hamilton (1964) proposed that costly acts could provide inclusive fitness benefits by helping individuals who share a proportion of your genes. Trivers (1971) removed the need for shared genes with reciprocal altruism. Trivers catalyzed the study of reciprocal altruism in his classic paper that formalized the concept, described its evolutionary preconditions, provided illustrative examples, and outlined the relevant psychological components. He proposed how natural selection could favor behavioral interactions in nonkin that yield overall net fitness benefits even if they produced immediate fitness costs. Reciprocal altruism recoups the immediate costs of altruism by emphasizing the long-term benefits of interacting repeatedly – you scratch my back, I'll scratch yours.

Trivers proposed evolutionary conditions needed for reciprocal altruism to evolve. First, the fitness benefits to the recipient of help must outweigh the costs to the cooperator. That is, after reversing roles helping has to result in a net fitness increase. Second, the probability of reciprocation must be high. Several factors may increase the probability of reciprocation, including (1) many opportunities for future altruistic situations, (2) repeated interactions with the same individuals, and (3) symmetrical exchanges in which the roles of donor and recipient reverse frequently

enough to result in roughly equal experiences at both roles.

Researchers have proposed a number of cases of reciprocal altruism across a broad range of species, from hermaphroditic worms to humans (Dugatkin 1997). Much of the data on reciprocal altruism involves correlations of altruistic behaviors between individuals. For example, vervet monkeys (*Chlorocebus pygerythrus*) are more likely to come to the aid of an individual who has previously groomed them (Seyfarth and Cheney 1984). There are, however, multiple types of reciprocal altruism. *Calculated reciprocity* involves tracking the precise actions of specific partners, along with the costs and benefits of those actions. Calculated reciprocity uses scorekeeping to ensure exact reciprocation, and this concept most closely matches the intuition behind “you scratch my back, I’ll scratch yours.” The first formal model of reciprocal altruism – tit-for-tat – is a strategy that exemplifies calculated reciprocity because cooperation is contingent on the partner’s cooperation in the last interaction (Axelrod and Hamilton 1981). Tit-for-tat strategists copy their partner’s last action: cooperate or defect (not cooperate).

Other, less precise mechanisms can also generate observed reciprocal correlations. *Attitudinal reciprocity* (Brosnan and de Waal 2002) and the similar notion of *emotional bookkeeping* (Schino and Aureli 2010) refer to situations in which altruism from a partner invokes positive attitudes/emotions toward that partner, which results in reciprocated altruism. Instead of precisely keeping track of previous actions, individuals track an overall emotional reaction to a partner. *Symmetry-based reciprocity* refers to reciprocal patterns of altruism that occur because of some symmetry in the relationship between two individuals (de Waal and Luttrell 1988). For example, if individual A and B often associate with one another but A and C rarely associate, A and B may be more likely to help each other due to their higher likelihood of interacting, whereas A and C will be less likely to help each other because they are rarely in contact. In symmetry-based reciprocity therefore, reciprocal altruism is a byproduct of some other symmetrical relationship, such as spatial proximity.

Researchers typically refer to these aforementioned types of reciprocity as cases of *direct reciprocity*, in which the reciprocal exchange occurs between two individuals. Other forms of reciprocity, however, involve more than just a pair of individuals. *Indirect reciprocity* refers to situations in which a third party tracks interactions between other individuals (Nowak and Sigmund 1998). If, for example, individual C observes that individual A helps individual B, then C would help A in a future interaction. Indirect reciprocity, therefore, uses third-party reputation rather than direct experience to reciprocate help. *Generalized reciprocity*, in contrast, does not track actions of specific partners. Donors help when they were helped in the previous interaction, irrespective of who helped them, thereby “paying it forward.” Thus, this form of reciprocity tracks only the actions of the last interaction regardless of partner (Pfeiffer et al. 2005).

These forms of reciprocal altruism have different psychological building blocks that are needed to implement reciprocal behaviors. For example, to use tit-for-tat, an individual must be able to recognize partners and remember their previous behaviors, which requires the building blocks of individual recognition and accurate memory. Understanding both cognitive and emotional building blocks is critical to the evolution of reciprocal altruism because the degree to which these building blocks are present can constrain what types of reciprocal altruism can evolve. Symmetry-based reciprocity may not require sophisticated psychological building blocks, because the reciprocity is a byproduct of other features of the relationship. Calculated reciprocity, in contrast, may require a number of building blocks to maintain the precise scorekeeping. Further, other psychological building blocks may not be required for reciprocity but may greatly facilitate its use.

Cognitive Building Blocks

Cognition refers to information processing, and cognitive building blocks are core cognitive abilities that process information. Though not all

cognitive building blocks are required for reciprocal altruism, several may be key, especially for calculated reciprocity.

Partner Identification

Reciprocal altruism involves reversing roles as donor and recipient with partners. Some mechanisms underlying reciprocity may require being able to identify partners. Both direct and indirect reciprocity, for example, require partner identification, though generalized reciprocity does not.

Individual Recognition

One cognitive building block that allows partner identification is individual recognition. Though humans take for granted the ability to recognize different individuals, other species may not be able to distinguish specific individuals from others. This may be especially true in species that do not have individually based repeated interactions, such as large swarms of invertebrates. Nevertheless, many species do recognize specific individuals. Social wasps, in particular, show remarkable abilities to use visual cues to recognize individuals: species that have complex social interactions also have highly identifiable physical features (Tibbetts and Dale 2007). Thus, the evolutionary pressures of social interactions may shape the degree of individual recognition that evolves.

Individual recognition may not be strictly required for all reciprocal interactions. Other cues such as location may act as a proxy for identity. Cleaner fish clients, for example, may return to the specific location to be serviced by the same cleaner fish (Trivers 1971). In this case, the clients do not have to recognize specific cleaners but simply remember a location.

Attributes of Payoffs

Though the ultimate currency of fitness is measured in terms of genes, animals make decisions about fitness proxies such as food, mates, predation risk, and habitat quality. Characteristics of these fitness payoffs have critical implications for processing information about them. For some payoffs, animals must be able to compare the quality of various options, or inhibit the impulse

to choose an immediately available, yet sub-optimal choice. Thus, certain cognitive building blocks are necessary to properly assess and decide between payoffs.

Quantification

Altruism involves a cost, which may require comparing two tangible fitness payoffs. These comparisons can be difficult since, across a wide range of species, large quantities are more difficult to discriminate than small quantities (Feigenson et al. 2004). In cooperative games, for example, Furlong and Opfer (2009) found that people cooperated more when the payoffs were described in U.S. cents (e.g., 300¢ vs. 500¢) compared to U.S. dollars (e.g., \$3 vs. \$5), even though the values were the same. When the values were larger and less discriminable, people cooperated more because it seemed less costly. Thus, the ability to quantify and compare the payoffs of various options can influence cooperation.

Inhibitory Control

After discriminating between fitness payoffs, individuals must choose between them. Since altruistic cooperation involves a cost and results in smaller payoffs compared to defecting, to cooperate, individuals must choose a smaller payoff over a larger one. Children and other species, however, have difficulty inhibiting a strong preference for larger rewards.

In the reverse-reward contingency task, individuals select between a small and large reward, but they must choose the smaller to receive the larger (Boysen and Berntson 1995). Young children and numerous species of primates fail at this task (Shifferman 2009), and special training is needed for them to override the strong preference for the larger payoff. Yet, the ability to forgo larger payoffs for smaller ones is exactly what altruism requires when given the choice between acting altruistically (and suffering a loss) or acting selfishly. Inhibitory control, an animal's ability to inhibit an immediately desirable response, can therefore facilitate reciprocal altruism. When fitness payoffs are presented sequentially instead of simultaneously, a lack of inhibitory control may not pose a problem for altruism.

Time Lag

By definition, reciprocal altruism involves a reversal of roles where an individual sometimes gives help and at other times receives help. In most cases of reciprocal altruism, a time lag exists between giving and receiving help. This time lag means that donors must wait before their help is reciprocated (Trivers 1971), which has critical implications for cognition because individuals may forget and have difficulty waiting for delayed payoffs.

Memory for Actions

Tracking the behavior of partners involves remembering either specific previous actions or overall summaries of actions for individuals. Tit-for-tat, for instance, requires remembering only the last action for a specific partner (Axelrod and Hamilton 1981). Though this is a rather simple memory problem for computers to solve, memory in humans and other species does not work like computer memory. Instead, natural memory systems are subject to error. Namely, they fall prey to two forms of interference: proactive and retroactive.

Proactive interference occurs when information already in memory interferes with the recall of new information. This is relevant for tit-for-tat because it requires recall of only of the last interaction with a partner. But it is possible that earlier interactions with that individual interfere with accurately recalling the most recent interaction. Retroactive interference occurs when new information interferes with the retrieval of older information. This is where the time lag between interactions becomes important, because often individuals have a number of social partners with whom they interact. Individuals likely interact with other partners between interactions with a particular partner. Therefore, these intervening interactions can interfere with accurately remembering the previous actions of a particular partner.

In a study of cooperative memory, Stevens et al. (2011) tested the impact of these two forms of interference on human memory. Though proactive interference did not impact memory, retroactive interference greatly reduced memory accuracy of previous partner actions. Increasing

both the overall number of partners as well as the number of intervening partner interactions degraded memory. Further, evolutionary simulations suggested that tit-for-tat and related strategies would have difficulty evolving with the memory errors rates demonstrated in the experiment. Thus, tit-for-tat's memory requirement of accurately recalling a partner's most recent action does not seem to match how human memory systems work. Importantly, other forms of reciprocal altruism are less subject to such memory constraints. Generalized reciprocity, for example, does not necessitate remembering what specific individuals do.

Memory for Individuals

Though calculated reciprocity requires tracking individual actions, other forms of reciprocal altruism do not. Attitudinal reciprocity and emotional bookkeeping require generating an overall impression of a partner and deciding to help based on that. Thus, rather than remembering individual actions, these forms of reciprocal altruism track a general impression of a partner, which seems much more amenable to actual memory systems (Bell and Buchner 2012).

One of the simplest forms of memory is recognition. Rather than remembering any content about an individual, recognition simply tracks whether the individual has been encountered previously. Aktipis (2006) demonstrated in a simulation that relatively simple memory strategies that simply recognized cooperators and only cooperated with individuals they recognized could maintain cooperation. So, simple recognition memory alone may allow cooperation to evolve.

In addition to recognition, individuals may remember an overall impression of a partner as a cooperator or defector. Cosmides and Tooby (1989) proposed that the costs of falling prey to defectors (cheaters) are so great that natural selection should favor individuals who can detect cheaters. Following this logic, researchers have tested whether people are better at remembering cheaters compared to cooperators, since, in general, missing out on the benefits of cooperation is not as costly as being cheated. In fact, evidence

suggests that people do have better memory for cheaters when the cheaters' misdeeds are described verbally, and this memory effect seems to be moderated by negative emotions associated with threatening information about the cheater (Bell and Buchner 2012).

In playing cooperative games against cooperators and cheaters, however, there does not seem to be a preference for remembering cheaters. Instead, people show a preference for remembering the rare type in the population (Barclay 2008). If there are many cheaters in the population, for example, remembering the cooperators provides a memory shortcut.

Patience

Another difficulty with time lags is that humans and other animals do not like to wait for delayed payoffs. Altruism requires forgoing larger, immediate payoffs, and reciprocity requires waiting to recoup the larger payoffs after a time delay. Reciprocal altruists, therefore, must be patient enough to wait for the reciprocated benefits. Waiting can be costly, however, because the future is uncertain – there is a risk that the partner might not reciprocate. This risk increases with the time delay for two reasons. First, the longer the delay, the more likely it is that something (e.g., death) interrupts the partner, preventing him/her from reciprocating. Second, the longer the delay, the more likely it is that the partner will forget to cooperate in return (see Memory for Actions). Therefore, the increased risk with time makes impatience evolutionarily rational as time delays increase.

When given choices between smaller, sooner and larger, later food options, nonhuman animals wait on the order of seconds or minutes for the delayed options, which is shorter than expected if they are maximizing the long-term rate of food intake per unit time (Hayden 2015). Humans also make short-sighted choices, preferring smaller, sooner options over larger, later ones, even when waiting provides better long-term payoffs, such as investing money in retirement funds (Frederick et al. 2002). Thus, humans and other animals have a difficult time waiting, which could constrain reciprocal strategies when long time intervals are involved.

Researchers have investigated this relationship between patience and cooperation by measuring them in the same individuals and correlating their responses. Human participants who can wait for delayed rewards also are more cooperative (Harris and Madden 2002), suggesting that patience is required for cooperation. To more directly test the effect of patience on cooperation, Stephens et al. (2002) directly manipulated patience in blue jays (*Cyanocitta cristata*) when playing a cooperative game. When the jays were experimentally induced to be more patient, they also cooperated reliably when paired with a reciprocating partner. Patience, therefore, is a key building block for reciprocal altruism.

Language

To avoid memory problems associated with the time lags inherent to reciprocal altruism, humans have evolved the ability to offload these transactions from memory onto physical objects via recordkeeping. In fact, archeologists propose that the earliest instances of symbolic writings are records of economic transactions rather than written transcriptions of language (Nissen et al. 1993). Basu et al. (2009) explored the effects of recordkeeping on individual economic behavior by demonstrating that allowing recordkeeping increases cooperative choices, reduces risky investments, and facilitates the formation of reputation in cooperative games. Thus, humans have evolved a workaround for the constraints of memory, and tracking cooperative interactions may have driven the evolution of written language.

Spoken language, though not a requirement, may greatly facilitate reciprocal altruism in a number of ways. First, it increases the precision of the altruistic exchange. In many cases, the fitness benefit and/or the time frame of a reciprocal exchange are rather abstract. Language allows more concrete exchanges because individuals can enumerate and describe benefits that may not be present at the time – for example, exchanging one goat now for 10 bushels of wheat after the harvest. It can also allow discussion of a future time frame, which is difficult to represent, otherwise. By specifying abstract concepts, language opens the possibility for formal contracts.

Language also provides a very flexible means to attempt to change the behavior of social partners through bargaining and coercion. Rather than requiring fixed exchanges, social partners can negotiate with language, describing multiple possible outcomes before settling on one. Moreover, a potential recipient can attempt to induce helping by imploring a potential donor with promises of future reciprocation or by cajoling the donor with warnings of withholding future help. The potential donor can, in turn, threaten the potential recipient with sanctions if the aid is not reciprocated. Language can allow for “cheap talk,” though; and enforcing the promises and threats can be difficult.

Language’s most powerful influence on reciprocal altruism is probably through indirect rather than direct reciprocity. Observing social interactions between others is a faster way to gain information about social partners than direct experience alone. Hearing about interactions that one did not directly observe opens the door to even more information about behaviors of social partners not witnessed by the focal individual. Thus, language greatly enhances the ability to track partner actions via gossip (Sommerfeld et al. 2007). In modern day social interactions, ratings provide an indispensable way for online sellers and buyers to trade goods for currency. With publicly visible ratings of their trustworthiness, sellers are forced to make good on their contract to provide good and services to buyers. For humans, language is an essential cognitive building block for multiple forms of reciprocal altruism.

Emotional Building Blocks

Emotional processes can also be important psychological building blocks for reciprocal altruism (Fessler and Haley 2003; Trivers 1971). In fact, attitudinal reciprocity and emotional bookkeeping critically depend on emotional building blocks. Though the emotional components are not well described for these forms of reciprocal altruism, they generally refer to a positive or negative affect directed toward individuals (Schino and Aureli 2010). These general emotional reactions are

akin to liking and disliking, and they facilitate the development of social bonds and friendships. Trivers (1971) suggested that, in humans, specific emotions may have evolved to facilitate reciprocal altruism, with different emotions associated with donating or receiving altruistic help.

Donor Emotions

Emotions experienced by donors help them detect a need for altruistic help in others and respond to instances of cheating.

Sympathy and Empathy

The first step a donor faces in an altruistic situation is to determine the degree to which a partner needs help. Sympathy and empathy are emotions that facilitate detecting partner need by attempting to understand others’ needs. Trivers (1971) suggested that these emotions motivate altruistic behavior based on need; the greater the need, the greater the sympathy or empathy. This emotional response may be necessary to overcome the cognitive impediments associated with strong preferences for maximizing current fitness payoffs for self (inhibitory control problems and impatience).

Trust and Betrayal

Donating help in a reciprocal way involves uncertainty since the partner may not reciprocate. This can occur in the time-dependent manner described previously (see Patience) or simply because the partner will choose not to reciprocate. Trust helps overcome an initial aversion to risk caused by the uncertainty associated with future reciprocation. When trust is validated by reciprocation, the level of trust will increase, and donors may be willing to accept greater altruistic costs. When trust is violated by cheating, donors experience the emotions associated with betrayal and withhold future altruism. Shackelford and Buss (1996) proposed that the emotion of trust betrayal serves two functions. First, betrayal motivates the donor to communicate the breach of trust to the partner, which may deter future cheating. Second, betrayal may prompt the donor to sever the relationship with the partner, preventing future exploitation. Betrayal can feed into the cognitive components of reciprocal altruism by highly weighting memories for

cheating by partners. Combined, trust and betrayal induce a donor to take a risk and help a partner – potentially reinforcing a strong positive relationship with that partner – but also track a partner's lack of reciprocation to minimize future cheating.

Anger and Moralistic Aggression

Though betrayal can motivate the rather mild response of communicating a breach of trust with a partner, it can also induce a stronger negative response by instigating anger or moralistic aggression. Trivers (1971) suggested that moralistic aggression protects against cheaters by (1) overriding positive emotions leading to continued altruism with that partner, (2) frightening the cheater into reciprocating, and (3) directly reducing the fitness of the cheater by injuring, exiling, or even killing him/her.

Anger can act as an honest signal of intention to punish and do harm. Sometimes the aggressive acts caused by anger seem out of proportion with the costs of cheating. If, however, there are many opportunities for future interactions, the benefits of inducing future cooperation may outweigh the costs of aggressive punishment (Trivers 1971). Moreover, anger can have strong reputational effects, such that third parties are induced to cooperate after observing or hearing about aggressive acts, even without direct experience with the angry donor. Thus, anger deters cheating in both direct and indirect reciprocity situations.

Recipient Emotions

Recipients have also evolved emotions associated with reciprocity, primarily to induce reciprocation.

Gratitude

Gratitude is appreciation for an altruistic act that serves three functions relevant to altruism (McCullough et al. 2001). First, it detects that a donor has provided a benefit to the recipient. This helps recipients track altruistic acts. Second, it motivates the recipient to pay back the altruistic debt in the future. Third, expressing gratitude toward a donor reinforces that donor's actions,

potentially increasing the likelihood of future altruistic behavior on his/her part. Trivers (1971) suggested that gratitude scales to the costs and benefits of altruism – the greater the costs and benefits, the greater the gratitude. This increases the motivation to reciprocate when the donor has accepted substantial costs or donated substantial benefits. Moreover, gratitude can overcome disliking individuals who have previously failed to reciprocate but have made amends (Trivers 1971). Gratitude, therefore, greatly facilitates reciprocal altruism by ensuring appropriately scaled reciprocation, inducing future altruism, and repairing damaged relationships.

Guilt

Guilt is the negative emotion that occurs when one has violated a moral or social standard (Kugler and Jones 1992). For reciprocal altruism, this occurs when a recipient has or is contemplating cheating rather than reciprocating. Following cheating, guilt may function to induce a cheater to correct the wrong either by immediately reciprocating or by compensating the donor in other ways (Trivers 1971). This allows the cheater to repair the relationship and avoid the long-term costs of never receiving altruistic support from the donor in the future. Anticipating the guilt associated with intended cheating also can motivate reciprocation. Guilt identifies, prevents, and repairs damage done to social partners, even if the damage was unintentional (Fessler and Haley 2003).

Conclusion

Psychology constrains the types of reciprocal altruism that can evolve, and models of reciprocal altruism without psychological constraints provide little predictive power. Species vary in what building blocks they possess, and, therefore, measuring these building blocks can focus attention on relevant types of reciprocal altruism. We cannot understand the evolution of reciprocal altruism without understanding the psychology underlying it.

Definition

The potential reframing of psychological abnormalities and pathologies as having adaptive, evolutionary fitness-maximizing attributes.

The scientific conceptualization of psychological abnormalities and pathologies has been steadily refined through developments in cognitive science, neurobiology, and neuroendocrinology. The role that genetic and epigenetic influences play in undergirding the neural and biochemical activity that influences human cognitive development and function is now well-established in the literature. Indeed, many mental

health conditions that have typically been referred to as “diseases” or “ailments” are probably normal instances of within-species phenotypic variation with respect to differences in cognitive and affective processing and subsequent behavioral output. Rather than being disabilities, conditions such as autism, synesthesia, and even major depressive disorder – each of which have an enduring presence in the human genome – might have played a significant evolutionary role in helping to broaden and diversify the constellation of cognitive and affective traits of humankind (Reser 2011).

Furthermore, the trade-offs that accompany many of these conditions might only be considered to be disadvantages per se when considered in the light of the modern sociocultural milieu in which we currently find our species embedded. Autism and attention deficit hyperactivity disorder (ADHD) are two fulsome examples in this respect (Kapp et al. 2013). While the constrained social and interpersonal faculties that are typical of autism spectrum disorders are often highly disadvantageous to sufferers living in the modern world – globalized, socially expansive, and highly characterized by access to a massive breadth of potential social relationships – the propensity to automatically and rigidly engage in impersonal, systematic thinking might have proven highly advantageous in ancestral times, where cognition unbiased by social obligation and expectation might have conferred a level of cognitive clarity to the individual that proved highly valuable in hunting and foraging activity, environment navigation, weather pattern assessment, and so forth (Spikins et al. 2016).

Likewise, those people suffering from ADHD, though often tremendously hamstrung in many modern environmental contexts such as schooling (where the capacity for steadfastness and patience generally allow for greater ease of learning), might have, through an ancestral framing, possessed a level of unpredictability and behavioral variability that could have lent itself to maximizing evolutionary fitness (Brüne and Brüne-Cohrs 2006). A 2008 (Eisenberg et al. 2008) study of two separate tribes in Kenya found that a nomadic tribe possessing the DRD4 7R receptor gene –

which is strongly associated with ADHD, as well as novelty seeking and spontaneity – was better nourished overall than the members of a settled tribe who possessed the same allele. The authors of the study surmised that, for nomadic populations (which would have characterized ancestral humans), ADHD-like behaviors with more diffuse attentiveness might have lent themselves to greater advantages in environmental scanning and anticipation of predatory and other environmental threats (Jensen et al. 1997).

The major upshot here is that what may currently be referred to as an instance of psychopathology may in fact simply be an instance of an adaptation or byproduct whose evolutionary affordances have been blunted or attenuated due to the discordant influences of modern life. What is now considered a “disease” by the lights of modern psychological science may have been a highly advantageous trait for those possessing it during the vast majority of human history.

Antisocial personality; Antisocial personality disorder (ASPD); Callous-unemotional traits; Fast life-history strategy; Sociopathy

Definition

Psychopathy is characterized by varying levels of four interrelated personality traits and behavioral tendencies: low levels of emotional reactivity (callous unemotionality, shallow affect, and boldness), glib interpersonal style (superficial charm, egocentricity, and deceitfulness), antisocial tendencies (poor behavioral control and aggression), and a parasitic lifestyle typified by impulsivity, irresponsibility, and a lack of long-term planning (Hare 2016).

Introduction

Psychopathy is of wide interest to clinicians, research psychologists, and the general public – likely as a result of human beings' vested interest in understanding (and guarding against) cheaters and social interlopers. While some unequivocally view the antisocial behavior and callous nature of psychopaths to be an obvious example of a human personality disorder (Crego and Widiger 2014), others note that these same traits can be thought of as adaptive (for the individual) inasmuch as they facilitate mining social groups for resources and opportunities (Krupp et al. 2013). A full understanding of whether psychopathy is disordered, adaptive, or neutral, is only possible after considering: (1) the way in which psychopathy manifests; (2) the development of psychopathy and whether or not it is indicative of normal

development gone awry or a suite of adaptive behaviors favored by natural selection; (3) the specific ways psychopathic traits are adaptive and confer either a survival or reproductive benefit to their carriers; and (4) whether selective forces could have favored and maintained traits associated with psychopathy across genealogical time.

Psychopathy in Context

Traditionally, psychopathy has been parsed into two distinct, yet somewhat overlapping, subtypes. *Primary psychopathy* is typified by a reduction (or absence) of social emotions, namely empathy, resulting in low emotional reactivity and a glib interpersonal style. *Secondary psychopathy*, which does not display the extreme shallow affect characteristic of primary psychopathy, is typified by impulsive actions, aggression, parasitic lifestyle, and the violation of other's rights – all of which are underpinned by callous-uncaring tendencies (Mealey 1995; Hare 2016). The uniting feature of both primary and secondary psychopathy is that both can lead to antisocial behavior and are underpinned by callous-unemotional traits.

The extreme (clinical) form of psychopathy occurs in roughly 1% of the general population, is more common among males, and is disproportionately represented among violent criminal offenders (Hare 2016). Although the concept of psychopathy initially grew out of psychiatry and clinical psychology (Crego and Widiger 2014; Mealey 1995), traits associated with psychopathy are normally distributed in the general population, often occurring at subclinical levels (e.g., Glenn et al. 2011). For this reason, it is often more useful to discuss psychopathic *traits*, which are somewhat normally distributed in the population, rather than psychopaths, who make up only a small percentage of humans. Because people with high levels of psychopathic traits tend to violate social norms, feel little to no guilt about their actions, engage in impulsive (sometimes reckless) behavior, and use deceptive charm and cunning to manipulate people to their own ends, their social strategies are necessarily short-term, often

resulting in volatile and short-lived personal and sexual relationships (Lalumière et al. 2009). Such a pattern of behavior is generally considered to be consistent with a “fast” life-history strategy that prioritizes immediate rewards over long-term stability, and employs short-term reproductive strategies focused on sexual relationships with low commitment and little to no parental investment (Glenn et al. 2011). Unsurprisingly, psychopathic traits are strongly related to low levels of agreeableness and conscientiousness, with the cardinal features of psychopathy being largely consistent across both adolescence and adulthood (Lynam and Gudonis 2005).

A Calloused Mind: How Does Psychopathy Develop?

Mealey (1995) suggested that primary psychopathic traits were predominantly the result of genetic and biological factors, whereas secondary psychopathic traits were the result of early life history experiences. This view holds that early childhood experiences serve as a relatively reliable indicator of the probable environmental conditions in adulthood. As such, it is hypothesized that early childhood experiences shift an individual's behavior to meet the demands of their environment. Negative early experiences purportedly shift an individual's behavioral tendencies to strategies that enable more successful navigation of a hostile, unpredictable environment. This would represent a “facultative,” or “contingent” shift toward a fast life-history strategy. Two decades of research have come to challenge this assumption, with two complimentary lines of evidence converging to suggest genetic and other biological factors are fundamental in mediating the expression of both primary and secondary psychopathic traits.

First, the callous-unemotional traits that underpin both primary *and* secondary psychopathy are substantially heritable, with 79% of the variance in unemotionality, and 70% of the variance in callous-uncaring tendencies being due to underlying variation in genetic factors (Henry et al. 2016), suggesting only minimal environmental impact.

Second, many characteristics commonly present among individuals who experienced negative childhood events – ineffective parenting, lower IQ, learning difficulties, higher fluctuating asymmetry, neurodevelopmental problems, etc. – are *not* found among psychopaths, making early environment an unlikely cause of psychopathic traits (Lalumière et al. 2009; Krupp et al. 2013). Given current evidence, it appears that the traits underpinning psychopathic tendencies and behaviors are largely heritable and not the result of negative childhood experience, thus calling into question why such antisocial traits would be tolerated by natural selection.

Adaptation or Disorder: Is Psychopathy and Advantage?

It is clear that psychopathic traits, and the behavioral outcomes they tend to produce, deviate from what is typical among humans. This difference, however, should not be taken as synonymous with disorder. Psychopathic traits appear to confer a selective advantage, or serve to increase Darwinian fitness, when demonstrated in the appropriate contexts. People with high levels of psychopathic traits (who we tend to think of as “true” psychopaths) rarely engage in actions that significantly harm their close kin, helping preserve their inclusive fitness (i.e., survival of close kin) (Krupp et al. 2013). Additionally, psychopaths have as many children as nonpsychopaths, and in many cases they reproduce *more* (Krupp et al. 2013). Indeed, psychopaths tend to be characterized by a unique pattern of sexuality involving early sexual debut, numerous short-term relationships, and the (false) signaling of mate-value and parental investment (Lalumière et al. 2009). Because of the obligate care-giving role that women have in rearing children, such a strategy would have been more successful (from a genetic point of view) among ancestral men than women, helping to account for the modern sex differences in psychopathic traits. That is not to say psychopathy doesn't exist among women, or that psychopathic women don't use their considerable charm and astute manipulations to beguile individuals in

their social environment (see Honey 2015; Verona and Vitale 2006). Simply put, psychopathic traits manifest differently across the sexes and likely result in differential behavioral (and genetic) outcomes. Given the advantages to the individual (at the expense of the group), the cluster of traits resulting in psychopathic tendencies has more in common with an adaptive suite of personality and behavioral predispositions than it does with a disorder in either socialization or neurodevelopment. Psychopathic individuals' tendency toward antisocial behavior, turbulent social relationships, and the harms of both on affected individuals are obviously problematic from a societal perspective. These same behaviors, however, are not inherently problematic from the standpoint of natural selection.

Callous by Design? Natural Selection and Psychopathic Traits

The exploitative and deceitful interpersonal style associated with psychopathic traits, and the subsequent lack of remorse, makes people high in psychopathy stand out among otherwise cooperative and social humans. There are two accounts for how human social groups could tolerate individuals with psychopathic traits across evolutionary time. The first holds that psychopathic traits emerge as a result of tumultuous, harsh, and unpredictable early environments, which serve to intensify underlying propensities toward callous social manipulation and result in a fast life-history strategy (see above). These traits would not be weeded out of the gene pool because they provide a selective advantage when elicited in response to these challenging environments. This account is plausible, but left unsupported by the data inasmuch as psychopathic traits are not associated with significant cognitive or developmental deficits, or abnormally adverse early life histories (Lalumière et al. 2009; Krupp et al. 2013).

The second explanation is balancing or frequency-dependent selection. Under these selection regimes, social species containing predominantly cooperative members can remain stable over time despite the presence of a small

number of habitual “cheaters” who only engage in self-interested behavior (Glenn et al. 2011). So long as cooperation is the dominant strategy, social relations in groups will remain stable, and the habitual cheaters will be able to take advantage of unsuspecting cooperators. Given the high heritability of psychopathic traits (Henry et al. 2016), and the fact that psychopathic traits confer an exploitative social advantage to their carriers (Krupp et al. 2013), balancing selection is a more likely mechanism for the maintenance of psychopathic traits in humans across evolutionary time. Additionally, psychopathic traits may become more or less common in certain human groups depending on the way various societal, geographic, and cultural milieus impact the relative success of these behavioral strategies (Glenn et al. 2011).

Conclusions

Psychopathy – characterized by charming, yet callous, unemotional, exploitative, and antagonistic interpersonal strategies, and impulsive, aggressive, and often reckless behavior – has garnered considerable attention from psychiatry, psychology, and the general public. While some may speciously consider psychopathic traits, and the social costs they impose on others, to be disordered behavior, it is more plausible that these traits are an example of an adaptive behavioral suite designed for the extraction of resources from social groups and the facilitation of short-term mating opportunities. This socially disruptive pattern of behavior has persisted in each generation because these few successful charlatans benefit from effectively cheating the predominantly cooperative human social system.

where individuals engage in deviant, irresponsible, and egocentric behaviors, while maintaining an inability to establish successful connections with others.

Introduction

Dr. Linda Mealey, an evolutionary psychology researcher who passed away at the age of 46, contributed greatly to the scientific field through her work on psychopathy, evolution, and genetics. This chapter will discuss and review Mealey's work on psychopathy, with the majority of the chapter focused on her 1995 paper, *The Sociobiology of Sociopathy: An Integrated Evolutionary Model*.

The author will highlight psychopathy, a condition which encompasses 3–4% of the male population and less than 1% of the female population (Mealey 1995; see the Antisocial Behavior Chapter [Hashmani and Jonason 2017] for details on sex differences in antisocial behavior). Psychopaths, whether criminal or not, exhibit egocentrism, irresponsible and unpredictable behavior, impulsivity, deception, manipulation, superficial charm, and an inability to form concrete personal relationships (Mealey 1995). In 1941, Hervey Cleckley provided a list of personality-based criteria by which psychopaths could be identified (Cleckley 1941). Currently, psychopathy is assessed using an updated set of criteria – Hare's Psychopathy Checklist Revised (PCL-R; Hare 1991). Oftentimes, clinicians use the PCL-R along with the Diagnostic and Statistical Manual of Mental Disorders (5th ed.; DSM-5; American Psychiatric Association 2013) criteria when diagnosing psychopathy.

Based on Mealey's work, this chapter will begin by providing an explanation of the terminology used to understand psychopathy, while clarifying the two subcategories – *primary* and *secondary* psychopathy. Next, the author will outline six key distinctions between the aforementioned subcategories, including (1) differences in emotions experienced, (2) intellectual versus social deficits, (3) genetic versus environmental causes, (4) age that behaviors are first presented,

Psychopathy (Mealey)

Talia Hashmani
University of Waterloo, Waterloo, ON, Canada

Synonyms

Antisocial personalities; Antisocial personality disorder; Sociopathy

Definition

Psychopathy is a mental disorder derived from either genetic or environmental risk factors,

(5) socioeconomic statuses, and (6) whether deviance is chronic or part of a fleeting lifestyle. Finally, the author will discuss preventative methods targeted at primary and secondary psychopathy, and suggest techniques to reduce their devastating impact on society.

Psychopaths in Society

Terminology

Clinicians, researchers, and the previous literature discuss psychopathy and its distinctions using varying terminology, portraying confusion and discrepancies across the psychological field. Such confusion results in a lack of consistency when labeling psychopathy, for instance, using the terms sociopathy, antisocial personalities, and antisocial personality disorder (ASPD) interchangeably or in replacement for psychopathy (Mealey 1995; Mealey and Kinner 2003; See the Personality Disorders Chapter [Hashmani 2018] for a detailed description of ASPD). Individual researchers may prefer one term to the other, as some may follow a categorical approach using the DSM-5 (e.g., ASPD; American Psychiatric Association 2013), while others may follow a typological approach, (e.g., a “psychopath” must have X traits, X socioeconomic status, and exhibit X behaviors, and a “sociopath” must have Y traits, Y socioeconomic status, and exhibit Y behaviors; Mealey 1995). For the purpose of consistency throughout the remainder of this chapter, the author will reserve the term “psychopath” for referring to primary and secondary psychopathic individuals and behaviors. In addition to the discrepancy regarding terminology when defining psychopaths, there is also a lack of clarity surrounding the distinctions and subcategories of such individuals. For example, in contrast to Mealey (1995) distinguishing between the subcategories of psychopathy as “primary” and “secondary” psychopaths, a portion of the literature refers to these distinctions as “simple” and “hostile” psychopaths. Thus, for the purpose of this chapter, the author will expand on Mealey’s work using the former terms.

What Is a Primary Psychopath?

According to Mealey, there are two main sub-sections/types of psychopaths – primary and secondary psychopaths. From the outside, these categories may present similarly (e.g., criminal behavior, manipulation); however, the author will outline six key distinctions throughout the following two sections. To begin, this section will examine traits of primary psychopaths, and will be contrasted in the following section by a discussion on secondary psychopaths. (1) Primary psychopaths are classified as individuals with a complete lack of social emotions. It is important to understand the two types of emotions – *primary* and *social* emotions. Primary emotions (e.g., fear, anger, disgust) are hard-wired, and directly related to survival and human evolution, while social emotions (e.g., guilt, shame, love) are more complex, cognitive interpretations of primary emotions, specific to humans (Mealey 1995). These social emotions (unlike primary emotions) are dependent on learning and socialization, and vary across cultures and individuals. Due to the fact that social emotions are not biological nor are they a prerequisite for survival, primary psychopaths are not equipped with the capacity to experience such sensations. Empathy, a common social emotion, is thought to develop through one’s theory of mind – a concept which psychopaths lack – leading to an inability to acquire this emotion (Mealey 1995, 1997; Mealey and Kinner 2003). (2) Although flawed at experiencing social emotions, primary psychopaths have no intellectual deficits, and endure pronounced social skills, an excellent ability to predict others’ behaviors, and an awareness of the discrepancy between their behaviors and societal expectations (Mealey 1995). (3) These individuals are genetically predisposed to psychopathy, and are less affected by environmental cues necessary for normal socialization and moral development – the opposite of secondary psychopaths. (4) Due to this genotype that leads them to an asocial lifestyle, primary psychopaths begin to present with deviant behaviors at an early age, since environmental risk factors (e.g., destructive social groups, poor childhood conditions) are not a requirement for the development of primary psychopathy. (5) Primary

psychopaths, due to their genetic predisposition, can come from all socioeconomic backgrounds, but in the absence of environmental risk factors, most psychopaths from the upper class will be classified as primary psychopaths. Mealey (1995) suggests that upper class children are less likely than lower class children to suffer harsh environmental conditions, and so when psychopaths come from upper class conditions, it is clear that there is a genetic predisposition rather than a poor environment contributing to psychopathy. (6) Finally, Mealey (1995) suggests that these individuals will likely present with asocial behaviors throughout their lives, since the genetic predisposition will remain constant, regardless of their environmental stressors.

What Is a Secondary Psychopath?

The above section outlined six key characteristics of primary psychopaths, which will be contrasted with secondary psychopaths. (1) Secondary psychopaths, unlike primary psychopaths, are capable of experiencing a spectrum of emotions, consisting of primary and social emotions. These individuals exhibit disruptive behaviors in the absence of emotional discrepancies; however (2), they demonstrate deficits in social skills, emotion-regulation, and problem-solving (Mealey 1995). Such deficits disadvantage children in relation to their peers, leading them to pursue alternative, destructive social groups where they can compete effectively, rather than pursuing prosocial counterparts who they may deem superior. (3) Secondary psychopaths are not equipped with a genotype that drives them towards disruptive behavior, but instead, their behavior is dependent on harsh environmental factors. Mealey (1995) suggests that children who experience events such as a disrupted family life, parental neglect, the use of punishment as opposed to rewards, and abuse have their development of appropriate social, emotional, and problem-solving skills disrupted. These children, with their poor skills, are then drawn to similarly rejected peers, leading to the formation of deviant groups, where asocial behavior is regularly reinforced, and thus, this pattern continues as a lifestyle. (4) Since a child's upbringing and social

groups are a huge factor in the development of secondary psychopathy, these individuals first present with disruptive behaviors later than their primary psychopath counterparts. (5) Due to psychopaths' poor upbringing, these individuals often come from lower socioeconomic statuses, where harsh conditions such as criminal parents, dangerous neighborhoods, and substance abuse are more common. Psychopaths from lower socioeconomic conditions are more likely to be classified as secondary psychopaths. (6) Lastly, these individuals may not exhibit chronic deviance, as their destructive goals and desires may fluctuate based on shifting life history patterns (e.g., age, statuses within groups, living situations, changing environmental contingencies; Mealey 1995, 1999).

Preventative Measures

Following a detailed review of what primary and secondary psychopathy entails, and the causes of these disruptive behaviors, the next question must examine: How can society prevent and minimize the impact of psychopathic tendencies? In order to address this question, recall that primary and secondary psychopaths present with six key distinctions, therefore, preventative measures may vary based on the individual's classification. Since primary psychopaths develop their asocial behaviors from a genetic predisposition, it is important to address their physiological arousal states, whereas for secondary psychopaths, it is important to target their environmental conditions, in an attempt to prevent psychopathic behaviors.

Primary psychopaths, with a physiotype encompassing a higher threshold for stimulation and an underlying hypoarousal condition, may require preventative measures targeted towards providing nonexploitative, thrill-seeking, and novel alternative experiences (Mealey 1995). When engaging in a disruptive act, these individuals look for a cost-benefit analysis of other alternatives in order to achieve their desired level of sensation seeking, while gaining high payoffs, and immediate gratification. If they are unable to find an alternative activity that may reap the aforementioned requirements, they may believe the disruptive act is their only option. If society were

to provide healthy alternatives that reach similar levels of stimulation and excitement, it is possible that primary psychopaths may turn to these activities instead of psychopathic behaviors. It is therefore important to ensure that positive alternatives are stimulating and rewarding enough to engage the psychopath and deter them from a similarly rewarding criminal act. Such alternatives include: stunt performing, racecar driving, and skydiving (Mealey 1995).

On the other hand, preventative methods for secondary psychopaths – individuals who are more responsive to environmental influences – should target early environmental risk factors, rather than physiological states. For example, parental training is a key intervention that may reduce the development of destructive patterns for secondary psychopaths. It is possible that asocial behaviors may be reduced, and prosocial behaviors may be reinforced by appropriate use of parental modeling, induction, and behavioral modification techniques (Mealey 1995). It is likely, however, that difficult children can elicit poor parenting, as exhausted parents may lose faith and become less effective. Mealey (1995) suggests that parents need assistance in identifying high-risk children, and instructions on how to approach such situations, which can be provided through parental training. Additionally, a second preventative strategy may be to increase the availability of rewarding, prosocial opportunities for at-risk youth from lower socioeconomic statuses. Such activities may include sports teams and extracurricular activities, where children can meet others and expand their social circles from similar at-risk youth to the general population.

Although this chapter has highlighted the contrasts between primary and secondary psychopaths, there is one preventative method that would support the reduction of asocial behaviors for both subcategories of psychopathy. Mealey (1995) suggests that when both primary and secondary psychopaths decide to engage in deception, they first and foremost take into account the past behavior of the victim (e.g., their likelihood of detecting deception or retaliating), rather than conducting a risk assessment from the fears and anxieties non-psychopaths feel in anticipation of

being caught. In order to tackle this concern, society must establish and enforce a reputation for high rates of detecting deception and a willingness to retaliate. In order to do so, Mealey (1995) recommends that society must deter crime by increasing the probability of detecting and identifying criminal behavior, while also establishing a reputation to retaliate by increasing the probability of incarceration. This strategy should effectively reduce psychopathy as a whole, since such individuals engage in disruptive actions based on the probability that they will not get caught or be retaliated against.

Conclusion

This chapter approached the topic of psychopathy from the evolutionary perspective of Dr. Linda Mealey's work. Psychopaths are individuals who present with deviant, irresponsible and egocentric behaviors, while engaging in asocial activities, such as criminal acts, deception, manipulation, and impulsivity. This chapter strives to provide an awareness of psychopathy and its causes, in order to facilitate treatment and preventative methods to reduce such behaviors. In doing so, the author began by providing clarification on the different terms associated with psychopathy, while defining the two subcategories – primary and secondary psychopathy. Next, the author discussed six key distinctions between these two subcategories (e.g., emotions experienced, genetic versus environmental causes, socioeconomic statuses) in an attempt to assist society in distinguishing between these deviant individuals. Finally, this chapter aimed to shine light on preventative measures that society can take in order to minimize the impact of these behaviors, such as providing stimulating alternatives to crime, early parental interventions, and increasing society's willingness to retaliate. By increasing our knowledge on psychopathy and strengthening the ability to differentiate between primary and secondary psychopaths, the hope of this chapter is to effectively target psychopathic behaviors and reduce their effect on society.

Psychosis

Timothy Razza
Nova Southeastern University,
Fort Lauderdale, FL, USA

Synonyms

[Psychoses](#); [Psychotic](#)

Definition

An absence of, or break in, reality contact.

Introduction

The term psychosis is used to refer to a severe form of mental illness which may include characteristic symptoms such as hallucination, delusions, and both thought and behavioral abnormalities. Diagnostically, psychosis is a primary aspect of psychiatric disorders including Schizophrenia and Delusional Disorder. Psychosis may result from various etiologies.

Psychosis

In general, psychosis denotes “a mental state characterized by a loss of contact with reality” (Klieger and Khadivi 2015, p. 9). Psychosis can be defined narrowly, in the case of the presentation of hallucinations and delusions, or more broadly as related to thought and behavioral abnormalities (Cardinal and Bullmore 2011). Historically, the term psychosis evolved a great deal, originally utilized to replace more stigmatizing terminology, then to refer to any form of serious mental illness, and currently as a reference to specific symptoms and expressed abnormalities in thought and behavior (McCarthy Jones 2015). Psychoanalytically, Sigmund Freud distinguished between neurosis and psychosis, theorizing that

psychosis represented a complete collapse of ego functioning.

According to the ICD-10 Classification of Mental and Behavioral Disorders (1992), psychosis refers to “the presence of hallucinations, delusions, or a limited number of severe abnormalities of behaviour, such as gross excitement and overactivity, marked psychomotor retardation, and catatonic behaviour” (p. 10). Diagnostically, psychotic disorders involve abnormalities in one or more areas including hallucinations, delusions, disorganized thinking, disorganized or abnormal motor behavior, and negative symptoms (American Psychiatric Association 2013). Hallucinations are defined as “perception-like experiences that occur without external stimulus” (American Psychiatric Association 2013, p. 87). Hallucination can occur through any of the five senses, with the most common being auditory and visual. Delusions are fixed beliefs that are unable to be dissuaded despite contradictory evidence (Minzenberg et al. 2008). Disorganized thinking, typically observed through an individual’s speech, may involve a variety of abnormalities including derailment or loose associations, tangentiality, or incoherence (American Psychiatric Association 2013). Disorganized or abnormal motor behavior may include catatonia, “repeated stereotyped movements, staring, grimacing, mutism, and the echoing of speech” (American Psychiatric Association 2013, p. 88). Negative symptoms represent an absence or restriction in typical cognitive and emotional functioning and/or expression and may include flat affect, deficits in communication, anhedonia, avolition, apathy, and asociality (Möller 2007). Disorders included in the DSM-5 (2013) classification *Schizophrenia and other Psychotic Disorders* include Schizophrenia, Delusional Disorder, Brief Psychotic Disorder, Schizophreniform Disorder, Schizoaffective Disorder, and Schizotypal Personality Disorder. Other diagnosed conditions such as major depressive disorder, bipolar disorder, and borderline personality disorder may also present with symptoms of psychosis.

Numerous organic and environmental etiologies have been identified for psychosis. Organic causes may include psychiatric illness described

above; neurological disorders or disease such as a cerebrovascular accident (CVA); delirium; endocrine disease, such as hypothyroidism; as well as immune and autoimmune disorders (Cardinal and Bullmore 2011). Environmentally, psychosis may result from severe stress, trauma, forms of deprivation, as well as the product of specific recreational and toxic substances (Cardinal and Bullmore 2011).

Conclusion

Psychosis is a form of severe mental illness that may present as altered perceptual experiences (hallucinations), irrational beliefs (delusions), thought and/or behavioral abnormalities, or negative symptoms including deficits in communication, socialization, and expression of affect. Psychosis may be present in various psychiatric conditions, organic illnesses, or as the result of environmental etiologies stress, trauma, or specific substance use.

Puberty in Boys

Alan Rogol and Kelly Mason
University of Virginia, Charlottesville, VA, USA

Synonyms

Development; Gonadarche; Maturation

Definition

“Stage of development during which secondary sexual characteristics appear and there is a transition from the sexually immature to the sexually mature stage” (Rosenfield et al. 2008, 531).

Introduction

Puberty is a critical period in an individual’s life history, characterized by the appearance of

secondary sexual characteristics and gonadal maturation, ultimately resulting in the ability to reproduce. This transition spans several domains, affecting growth, body composition, metabolism, reproductive function, and psychological development.

Aberrant pubertal timing and/or progression may herald underlying pathology and has the potential to cause significant psychosocial distress. However, it is important to note that there is a large natural variability in the onset and progression of pubertal maturation with some individuals maturing earlier or later or more rapidly or slowly than others. Although within the statistically normal range, earlier or later pubertal maturation may greatly affect an adolescent’s psychosocial development.

Puberty: Regulation, Variability and Pathology

The onset of puberty is closely regulated by an intricate network of neuroendocrine signals. Gonadotropin-releasing hormone (GnRH) produced in the hypothalamus acts on the pituitary gland to stimulate the release of gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Luteinizing hormone is responsible for stimulating the testicles to produce testosterone, which travels to target organs to induce virilization and changes in body composition, bone density, and growth. Testosterone also acts indirectly to regulate its own secretion through peripheral conversion to estradiol, which, in turn, suppresses GnRH and gonadotropin secretion (Navarro 2012). Unlike LH or testosterone, FSH acts within the testicles to stimulate enlargement of seminiferous tubules and promote spermatogenesis, thereby inducing testicular enlargement (Abreu and Kaiser 2016).

The mechanism underlying pubertal induction was largely unknown until the 1960s. At that time, it was attributed to reduced sensitivity of a “gonadostat” to the negative feedback exerted by sex hormones. It is now widely accepted that pubertal onset is triggered by changes in the

frequency of GnRH pulses driven by the hypothalamic GnRH pulse generator (Rosenfield et al. 2008).

Subsequent discoveries have shed light on a complex network of integrated neuroendocrine signals that closely regulate puberty. These include proteins such as MKRN3, NKB, and kisspeptin, which mediate puberty via effects on hypothalamic GnRH secretion leading to downstream effects on gonadotropin and testosterone secretion (Navarro 2012; Abreu and Kaiser 2016).

This so-called hypothalamic-pituitary-gonadal (HPG) axis is active well before adolescence, both in utero and shortly after birth, during a period termed the “mini-puberty.” This is followed by the juvenile pause, a quiescent period characterized by small, irregular, widely spaced GnRH pulses and low gonadotropin levels (Sisk and Foster 2004). During late childhood, before physical evidence of pubertal maturation emerges, integrated inputs lead to a reactivation of the GnRH pulse generator. GnRH pulses increase in both amplitude and frequency as sensitivity to sex steroid decreases. This results in increased pulsatility at night with waxing and waning levels of gonadotropins and sex steroids during the day. As time progresses, GnRH pulses become more consistent, resulting in less variability in the level of sex steroids throughout the day. Interestingly, testosterone maintains a diurnal pattern with levels peaking in the morning and declining throughout the day but becomes less pronounced as maturation continues (Fuqua and Rogol 2013b).

Like testosterone, other hormones produced within the testes fluctuate during different phases of maturation. Anti-Müllerian hormone (AMH), for example, declines at the time of puberty as testosterone levels increase (Aksiglaede et al. 2010) but may remain high in boys with delayed puberty. On the other hand, AMH levels are low in gonadotropin deficiency and in patients with testicular dysfunction (Edelsztein et al. 2016). As with AMH, inhibin B is a glycoprotein produced within the testicles. It reflects testicular function via its feedback on the pituitary gland and effects on FSH secretion.

A comprehensive history and physical examination are critical for evaluating pubertal onset

and progression. When assessing pubertal maturation, it is important to differentiate pubarche from gonadarche. Pubarche refers to the development of pubic hair, which occurs in males at a mean age of 12 years, either before or after gonadarche. Gonadarche typically occurs at a mean age of 10 years. It may be identified clinically when testicular volume reaches >3 mLs, as assessed by a Prader orchidometer, a set of ellipsoid beads of known volume used to measure an individual’s testicular size. Pubertal stage is determined using a system developed by Marshall and Tanner in 1970, which incorporates age ranges at various stages of maturation (Marshall and Tanner 1970).

An accurate measurement of height is critical to a comprehensive physical assessment. Review of a child’s growth chart provides valuable insight into their pubertal maturation. The pubertal growth spurt is comprised of three phases. The first phase occurs prior to the onset of puberty and is characterized by a slight decline in the rate of height gain. This is followed by the most rapid growth or peak height velocity (PHV), which approximates 9.5 cm per year and occurs in mid to late puberty at a mean age of 13.5 years (Tanner and Davies 1985). Growth then slows significantly before fusion of the growth plates occurs and growth is complete.

Failure to demonstrate appropriate pubertal growth should raise suspicion for delayed puberty, defined as lack of testicular enlargement by age 14, and should prompt referral to a pediatric endocrinologist. However, children often present to medical attention well before they reach 14 years of age due to lack of secondary sexual characteristics or psychosocial concerns related to short stature and delayed development and their effects on quality of life.

Sports are often a major focus of preadolescent and adolescent males. It is at this time that there may be the greatest difference in size, strength, and power because of the physiologic alterations in pubertal maturation. Many small/slight boys know the distress of not being able to compete or being chosen “last” in pick-up games. Organized sports, except for those based on weight classifications (e.g., wrestling), are often formed

around age group categories. To paraphrase Dr. James Tanner (of the Tanner stages defining pubertal maturation and progression)...“to tell me that a boy is 14 years old is hopelessly vague” – is he a boy of 14, for example, with constitutional delay of growth and puberty or is he an emerging adolescent, virtually fully mature.

Young athletes are usually grouped by calendar age when considered for training or competition purposes. However, as noted above, it is well-known that youth of similar chronological age may differ greatly in biological maturity. A 14-year-old male may be completely prepubertal, but a 12-year-old may be fully mature with concomitantly much greater height, weight, and strength. Individual differences in growth and maturity may lead not only to competitive inequality but also to increased risk for injury due to overuse of structures (e.g., joints) not optimized for the training load or due to contact or collisions between athletes of vastly different body mass.

Bio-banding or the grouping of children based on physical attributes rather than chronological age is actually not a new concept – in the early twentieth century, for example, the development of pubic hair was considered an outward sign of readiness to do *adult* work (Cumming et al. 2017).

Bio-banding groups young athletes by maturity status, which may be based on secondary sexual characteristics (still subjective, in part, by physical examination), skeletal age (with the vagaries of standards and subjective interpretation) or by the percentage of predicted adult stature (estimate of maturity status), and the maturity offset (estimate of maturity timing, using peak height velocity as an estimate of status – either pre- or post-PHV, a reliable biological anchor of growth and maturation) (Malina and Cumming 2004).

Emerging evidence suggests that bio-banding, as an adjunct to age group competitions, can benefit both early and late maturers (Cumming et al. 2017). For a more complete discussion of this concept including some of the physical and psychological considerations, see Edge: Growth and Maturation <http://edge-growth-maturation.net.technion.ac.il/>.

When evaluating a child with delayed puberty, it is important to distinguish those with true pathology from those with “late blooming” or constitutional delay of growth and puberty (CDGP). Constitutional delay of growth and puberty is characterized by a *delay* in the timing and potentially tempo of maturation. Height velocity may appear slow as affected children continue to grow at a prepubertal rate as opposed to peers undergoing their pubertal growth spurt. Evaluation should include determination of a child’s bone age, as assessed by a radiograph of the left hand, which appears younger than chronological age (Styne and Grumbach 2016). When plotted against bone age rather than chronological age, the height of a child with CDGP appears normal and more consistent with parental heights. A family history of late blooming is not uncommon, and children often reach their genetic potential *without* intervention. Spontaneous puberty occurs by 18 years of age; however, testosterone therapy has the potential to reduce the psychosocial distress that frequently accompanies delayed puberty.

Although some studies have shown little effect of CDGP on psychosocial well-being (Zhu and Chan 2017), others demonstrate an association with poor psychological outcomes. In fact, many of these negative outcomes persist into adolescence and young adulthood. The Oakland Growth Study, for example, found that late-maturing boys were not only perceived as less mature and less attractive than peers but also had more feelings of inadequacy, which persisted into adulthood (Fuqua and Rogol 2013). Delayed pubertal timing has also been associated with higher rates of depression, anxiety, and substance use in adolescence and young adulthood. Academic achievement may be adversely affected as well (Zhu and Chan 2017).

Unlike CDGP, in which pubertal onset occurs spontaneously, delayed puberty may also occur in those with permanent hypogonadism, caused by failure to produce sufficient levels of testosterone, sperm, or both (Basaria 2014). Hypogonadism may be subdivided into hypo- or hypergonadotropic hypogonadism. Hypogonadotropic hypogonadism, also known as secondary

hypogonadism, occurs when there is a defect in the production or secretion of FSH and LH, resulting in small testicular size, insufficient sperm production, and low testosterone levels. Low testosterone may also occur in testicular dysfunction. Lack of feedback at the level of the pituitary gland results in elevated gonadotropin levels, leading to hypergonadotropic hypogonadism or primary hypogonadism.

Hypogonadotropic hypogonadism may occur in a variety of settings. It may develop in children with traumatic brain injury or other disorders of the CNS. Given that gonadotropins are produced within the pituitary gland, hypogonadotropic hypogonadism may be detected in hypopituitarism with multiple pituitary hormone deficiencies or in the absence of pituitary dysfunction, an entity termed isolated hypogonadotropic hypogonadism (IHH). Isolated hypogonadotropic hypogonadism is a heterogeneous disorder, characterized by insufficient production of FSH and LH resulting in a low testosterone state. Some feel that it may fall on a spectrum of delayed maturation, opposite from CDGP. Table 1 outlines notable distinctions between IHH and CDGP.

The term Kallmann syndrome is applied when IHH is associated with a defective sense of smell. It results from abnormal embryonic migration of

GnRH neurons from their origin in the olfactory placode to the hypothalamus, leading to both hypogonadism and anosmia. Normosmic IHH is thought to be due to a defect in one of the many genes involved in the regulation of GnRH secretion, such as those coding for kisspeptin, kisspeptin receptor, neurokinin B, leptin, or leptin receptor. Leptin is a cytokine produced by white adipose tissue that regulates satiety and conveys metabolic status to the CNS. Children with a defect in either leptin or its receptor develop severe hyperphagia and early-onset obesity and fail to enter puberty appropriately. Interestingly, maturation ensues with leptin replacement therapy, highlighting its role in both puberty (Farooqi and O’Rahilly 2005) and metabolism. As seen in females with calorie restriction, males also experience hypogonadotropic hypogonadism in response to relative energy deficiency, potentially due to alterations in leptin signaling (Fuqua and Rogol 2013a).

Hypogonadism associated with elevated gonadotropin levels (hypergonadotropic hypogonadism) may be detected in a variety of disorders, most notably Klinefelter syndrome. Klinefelter syndrome occurs in 1/500–1/1000 males and is the result of meiotic nondisjunction, resulting in excess X chromosomal material, most often 47, XXY. Classic features include tall

Puberty in Boys, Table 1 Clinical and laboratory findings in IHH and CDGP

Feature	IHH	CDGP
Hormonal profiling during “mini-puberty” at 4–8 weeks of life	Lack of appropriate rise in LH and testosterone	Elevated LH and testosterone levels
Pubertal onset	Absent or pubertal arrest (less common)	Delayed; spontaneous progressive maturation by age 18
Puberty pattern	Absent or arrested gonadarche	Delayed pubarche and gonadarche
Growth	Prepubertal growth; +/- euchanoidal proportions (delayed growth plate fusion)	Normal growth for bone age
FH of delayed puberty	+/-	+/-
Sense of smell	+/- anosmia (30–50%)	Normal
Testicular size	Small testes (1–2 mL); +/- history of cryptorchidism	Normal for bone age
Stretched penile length	+/- micropenis	Normal for bone age
Possible associations	Bilateral synkinesis (mirror movements), dental agenesis, renal anomalies, hearing impairment, midline defects (cleft lip/palate)	None

stature, behavioral disorders, motor dysfunction and mild-to-moderate deficits in language-based skills, and attention and auditory processing (Wosnitzer and Paduch 2013). The vast majority of males who are diagnosed postnatally present with developmental concerns (Visootsak et al. 2013) long before delayed puberty is detected. Parents often become concerned about their child’s development before children come to the attention of pediatricians, neurologists, and psychologists leading to a 2–5-year delay in diagnosis.

Appropriate care for individuals with Klinefelter syndrome should be multidisciplinary, as affected individuals require both medical and mental health services through every stage of their lives. Many children have ADHD, and up to 86% require special education services (Close et al. 2015). Furthermore, many children report poor quality of life, and it is estimated that nearly 70% of adults experience depressive symptoms (Close et al. 2015). The exact cause of the neurocognitive and psychosocial disorders that often accompany Klinefelter syndrome is unknown, though some speculate that the lack of androgen effect on early brain development may play a role. In fact, androgen therapy has been shown to improve visual-motor performance, anxiety/depression, and social functioning when administered to prepubertal boys (Ross et al. 2017). However, testosterone treatment is not typically initiated until early adolescence when pubertal arrest occurs.

Hypergonadotropic hypogonadism may also be detected in children with a history of malignancy arising from radiation directed to the gonads or pelvis or exposure to chemotherapy. Alkylating agents in particular have the highest rates of gonadal injury. Given the potential effects on future fertility and psychological implications, it is recommended that individuals undergoing cancer treatment be counseled on the risks of infertility and potential for fertility preservation prior to the onset of treatment (Rose et al. 2016).

Testosterone may be used in the treatment of boys with delayed or absent puberty to induce virilization, enhance linear growth, promote bone health, and improve psychosocial well-

being. A relatively low starting dose is used in young children with gradually escalating doses over approximately 24 months to mimic natural puberty. This allows for development of secondary sexual features while maximizing linear growth. It is important to note, however, that testosterone therapy does not improve fertility or stimulate testicular growth. Evidence of testicular enlargement during testosterone therapy suggests a diagnosis of CDGP or reversal of IHH (Boehm et al. 2015). Side effects occur rarely and include acne, gynecomastia, aggressiveness, dyslipidemia, and polycythemia.

As with delayed puberty, puberty that occurs too early may also have psychosocial implications. Precocious puberty is seen much less frequently in males than in females and is defined as maturation that occurs before the age of 9 (Herman-Giddens et al. 2001; Abreu and Kaiser 2016). It may be the result of a gonadotropin-dependent or gonadotropin-independent process. Gonadotropin-dependent precocious puberty may arise from a variety of CNS disorders, such as tumors, cerebral palsy, or traumatic brain injury. Table 2 lists potential causes of gonadotropin-dependent and gonadotropin-independent precocious puberty. In up to 50% of cases, however, no identifiable etiology is discovered. A portion of these cases may involve dysregulation within the complex network that regulates puberty. In fact, whole

Puberty in Boys, Table 2 Causes of gonadotropin-dependent (central) and gonadotropin-independent (peripheral) precocious puberty

Gonadotropin-dependent	Gonadotropin-independent
Genetic disorders	Genetic disorders (familial male-limited precocious puberty, McCune-Albright syndrome)
Previous exposure to chronic sex steroids	Severe chronic hypothyroidism (Van Wyk-Grumbach syndrome)
Tumors (hypothalamic hamartoma, optic gliomas)	Tumors (adrenal or testicular)
CNS malformations	
CNS infections/inflammation	

exome sequencing of several families with gonadotropin-dependent precocious puberty led to the discovery of MKRN3 (Abreu et al. 2013), a protein thought to play an important role in the inhibition of puberty (Macedo et al. 2014). The MKRN3 gene is maternally imprinted; thus mutations that alter protein function are paternally inherited and associated with precocious puberty in both males and females. While there are several studies on the psychosocial effects of female precocious puberty, data in males is limited.

Conclusion

Puberty is a unique period characterized by the development of secondary sexual characteristics, ultimately culminating in the ability to reproduce (Rosenfield et al. 2008). This critical transition impacts not only physical appearance but also social and psychological well-being (Zhu and Chan 2017).

Puberty is regulated by a complex network of neuroendocrine pathways with natural variability in onset (timing) and progression (tempo). Early or late puberty may indicate underlying pathology and has the potential to cause significant psychosocial distress. In fact, individuals with pubertal disorders frequently come to medical attention as a result of psychological or neurocognitive rather than pubertal concerns.

Synonyms

Adolescence; Menarche; Reproductive maturation

Definition

Puberty in girls involves the maturation of the endocrine system resulting in the achievement of adult body size and proportions, secondary sexual characteristics, and development of the reproductive organs resulting in the capacity to reproduce.

Introduction

Puberty is a significant life history event marking the end of the prereproductive, juvenile phase of development, and entry into adulthood and reproductive life. Its characteristics, sequelae, and timing differ across species and between the sexes. Puberty in human females exhibits consistencies with the development of other mammals and primates, but unique qualities as well. Because puberty in girls is associated with a host of reproductive, medical, mental, and social changes, it has been the research focus of human biologists, physicians, psychologists, anthropologists, sociologists, demographers, and epidemiologists alike. Evolutionary theories and concepts, including life history theory, sexual selection, reproductive strategies, mate choice, conditional and alternative strategies, and parent-offspring conflict offer means to organize and synthesize the plethora of findings regarding puberty in girls.

Development and Puberty Within a Life History Approach

Development has been shaped by a long process of natural selection acting upon the developmental trajectories of individuals, resulting in species-specific life histories. Energetic resources available to organisms are finite and life history theory describes how fitness is optimized in different species through the nonrandom allocation of resources to maintenance, growth, and reproduction (Roff 2002; Stearns 1992). Typical life history traits include size at birth, growth pattern, age of sexual maturation, size at maturity, age of first reproduction, number and sex ratio of offspring, age- and size-specific reproductive investments and mortality schedules, and length of lifespan. Life history theory predicts trade-offs between energetic investment in growth, maintenance, and reproduction. Such adaptive patterns of allocation are referred to as life history strategies, whereas reproductive strategies describe the differential allocation of resources to mating and parental effort. Life history traits vary as a function of phylogenetic constraints and the different environmental selective pressures acting on male and female members of a species over their evolutionary history. From this perspective, puberty is envisaged as set of developmental processes nested within the overall species-specific human life history. As such its timing and characteristics are phylogenetically constrained, sexually differentiated, and intrinsically associated with other human life history traits.

Typical Characteristics of the Human Life History and Sexual Differentiation During Puberty

Homo sapiens is a relatively long-lived, large bodied species with a slow tempo of development. Production of altricial (defenseless and dependent) young, a long period of dependency, late sexual maturity and first birth, wide birth spacing, low offspring number, and high levels of parental investment, including postreproductive investment (grandparenting), are typical of the human

life history. While infant, juvenile, and adult stages are shared with other social mammals and primates, humans uniquely exhibit an extended period of sociosexual maturation between the two latter stages, referred to as adolescence, and a distinct postreproductive phase. When the human life history emerged is not known, but fossilized dentition indicates that the life history of ancient members of the genus *Homo* was closer to that of African apes rather than modern humans. Converging evidence suggests that the prolonged life history of *H. sapiens* emerged at least 160,000 years ago, following the appearance of *Homo erectus* in the late Pleistocene era (Bogin and Smith 1996; Dean 2006; Smith et al. 2007).

Insofar as they invest differing amounts of energy in reproduction (Trivers 1972), the two sexes may be expected to exhibit different life histories. Female mammals invest greater energetically in offspring than males, and their smaller adult body size reflects a tradeoff that has occurred between reproduction and growth. Males, on the other hand, invest more in mating effort and male-male competition for which a larger body size is advantageous. Human females and males differ not only in the overall pattern of energetic investment in growth versus reproduction but also on other life history traits, including the relative timing of puberty, the onset of fertility, mortality rates, and life expectancy. The typical human female life history, as illustrated in extant hunter-gatherer populations, involves a long juvenile period leading up to a relatively late age at puberty (average age at menarche 16–17), followed by a period of adolescent subfertility and first birth around 19–20 years of age, wide birth spacing (3–4 years), production of an average of 5 offspring, last birth around 39 years of age, menopause around age 47, and a postmenopausal phase lasting up to 70 or more years of age (Howell 1979; Lancaster and Kaplan 2009) (Fig. 1).

Although producing relatively few offspring, human beings successfully raise about 60% of their infants to adulthood compared to around 35% for their nearest relative, the chimpanzee. (Lancaster and Kaplan 2009). Higher survivorship may be linked to the advantages provided by the evolution of bipedalism and increased

Puberty in Girls, Fig. 1 Life histories of female hunter-gatherers (*Homo sapiens*) and chimpanzees (*Pan troglodytes*) (After Bogin and Smith 1996; Lancaster and Kaplan 2009; Walker et al. 2018)

brain size in hominins, in turn facilitated by later puberty and the unique growth pattern of human females. The evolution of bipedalism altered the pelvis, constraining the birth canal and restricting the somatic and brain size of human neonates. Human offspring are born altricial, but postnatal diversion of energy results in rapid expansion of the brain, while somatic growth slows. Once adult brain size is approached rapid skeletal growth and puberty occur. In most primate species, reproduction follows the onset of puberty within a few months to a year, but in humans a delay up to 5–10 years often occurs. This pattern of development suggests a unique trade-off between energy invested in body growth versus brain development (Bogin 2011) facilitating increased encephalization (ratio of brain volume to body size). Adult human brains are 3–4 times larger than those of our closest cousins, the chimpanzees. Achievement of adult body size before first pregnancy also means that maternal energy stores may benefit the neonate and its growing brain. Moreover, delayed puberty in girls and later first births permit a period of maternal psychological and social growth, and the acquisition of

parenting skills, together contributing to the enhanced survivorship of human offspring. Thus, the relatively slow life history of humans, with sexual maturity not occurring until late in the second decade of life, appears to be part of an adaptive suite of human traits, including an extended period of intense brain growth and learning, heightened parental care, increased adult brain size, enhanced cognitive abilities, and long lifespan distinguishing our species from other primates (Kaplan et al. 2000, 2007).

Sequence of Puberty in Girls in the Context of Mammalian and Primate Evolution

Girls' puberty involves a sequence of events emerging during primate evolution that transformed the juvenile phenotype (observable characteristics) into the adult form. Although humans do not undergo the spectacular metamorphoses observed in insects, the morphing of juvenile features into adult physical characteristics at puberty, especially in girls, is an overtly distinct phase, not

equally witnessed in other mammals or primates. Both girls and boys in industrialized nations undergo puberty earlier than typical for our species (see discussion of the secular trend), but the sequence of pubertal events remains invariant. Classic studies by Tanner and his colleagues (e.g., Eveleth and Tanner 1976; Tanner 1962) described the stages of pubertal development in modern girls according to the development of primary and secondary sexual characteristics:

1. Development of the breast bud (*thelarche*) is usually the first sign of puberty in girls and appears around 10–11 years of age. It takes 3–4 years for full breast development to occur. Development of breast buds is a noteworthy feature of human development, because other primate females do not develop breasts until the later stages of pregnancy. In those species, increased glandular tissue at pregnancy is resorbed again after weaning, while mature human breasts are continuously conspicuous and their size stable because they consist mainly of fat deposits.
2. Pubic hair begins to grow (*pubarche*) a little later under the influence of adrenal androgens as the adrenal cortex matures (*adrenarche*).
3. The ovaries, uterus, and vaginal canal then begin to increase in size.
4. An increase in height and weight, the growth spurt, begins around 10 years of age and intensifies.
5. *Menarche*, or first menstrual period, occurs fairly late the process, usually after the peak of height growth, with an average age of 12–13 year in North American girls, and a range of 9–18 years. At first menstrual cycles are irregular and many are anovular (an ovum is not produced). Apter and Vihko (1984) found over 50% of cycles were anovulatory in the first 2 years following menarche. During this period of adolescent subfertility, the probability of pregnancy is reduced.
6. The achievement of adult capacity of the pelvic inlet and birth canal, one of the most crucial features of reproduction, is not attained until the very end of the sequence of pubertal events, years after menarche. For example, in well-

nourished girls with menarche at 12–13 years, adult pelvic dimensions are not reached until 17–18 years of age.

The proximate trigger for the initiation of puberty is increases in the production of hormones (e.g., estrogen, testosterone, progesterone, growth hormone) as a result of changing activity in the hypothalamic-pituitary-gonadal (HPG) axis. In monitoring environmental and internal physiological conditions, the hypothalamus secretes releasing factors to the anterior pituitary, which in turn releases luteinizing hormone (LH), follicle-stimulating hormone (FSH), and growth hormone (GH). Growth hormone increases growth throughout the body, facilitating a rapid increase in height and weight. In girls, LH and FSH act on the ovaries, causing the release of estrogen and progesterone, which stimulate development of breasts, fat distribution, the uterus and its linings, and broadening of the hips. In boys, FSH and LH act primarily on the testes stimulating spermatogenesis and the production of testosterone. Testosterone is responsible for the development of male secondary sexual characteristics, including voice change, muscular and skeletal development (e.g., broadening of the shoulders), development of the seminal vesicles, penis and scrotum, and growth of hair on the chest, underarms, and pubic area.

In altering the timing of developmental events and the expression of somatic traits, the HPG axis is one of the physiological systems that has likely played an important role in the differential evolution of mammalian development and life histories. Ancestral selection pressures acting on the genetic substrate underlying the developmental inhibition and activation of the HPG axis have conserved some developmental features across species, but produced unique features in others. During human fetal development, a positive feedback loop in the HPG axis stimulates the production of FSH and LH and the hormones responsible for the initial development of the external genitalia. After birth, however, the HPG axis switches to a negative feedback loop. Detection of circulating steroid hormones by the hypothalamus inhibits the release of FSH and LH, and further sexual

development is paused until the onset of puberty. This pattern of activation followed by inhibition results in the long juvenile period of growth and development typical of humans and shared with many species of monkeys and all apes. However, as puberty is approached, the HPG axis switches back to a positive feedback loop and the completion of sexual development begins. As the HPG re-activates, the resulting heightened velocity of human growth contrasts with that of other mammals, including apes. While slow constant growth during the juvenile phase is conserved across these species, the acceleration of skeletal dimensions around the onset of human puberty, known as the growth spurt, is absent in other nonhuman primates whose growth decelerates around this time (Bogin and Smith 1996).

Sexual Bimaturism, Sexual Dimorphism in Size and Shape, and the “Fat Spurt”

Throughout childhood, boys and girls grow at a similar rate; however, prior to puberty their patterns of growth diverge. The growth spurt in height occurs a couple of years earlier in girls than in boys. In general, girls mature earlier than boys, a phenomenon referred to as *sexual bimaturism*, and this can be seen early in the first year of life as girls pass the developmental milestones before boys. Because boys grow slower, their long bones have an extra few years to grow before skeletal maturation is completed with the closing of the epiphyses (growth plates on the bones) (Tanner 1962; Limony et al. 2015). This results in men being on average taller and heavier than women, a phenomenon referred to as *sexual dimorphism* in size.

During childhood, girls and boys have a similar body shape and composition, but over puberty girls' and boys' body shapes and their distributions of fat and muscle undergo rapid transformation and divergence. One of the most obvious differences between girls and boys is the changing ratio of shoulders to hips. Girls reach the peak of their shoulder growth before their height spurt, but their hips begin to grow after the height spurt and the pelvis only reaches its adult growth in late

adolescence. Boys develop larger shoulders and torsos (upper body strength) over puberty, as a result of the laying down of muscle tissue in the chest and shoulder regions under the influence of male hormones (Winick 1981). Over puberty the proportion of muscle mass in boys increases significantly over that of girls. For example, in young adult males muscle tissue represents about 52% of body weight, whereas in girls it represents about 40%.

Fat tends to accumulate in children from 7 to 8 years old, but during the height spurt a loss in fat occurs in boys and the accumulation slows down in girls. Shortly after the height spurt ends, fat begins to accumulate again, especially in girls, who lay down twice as much fat as boys over adolescence. The increased deposition of fat or “fat spurt” occurs normally in girls during adolescence, regardless of their eating habits. The primary sites of fat accumulation include the thighs, hips, breasts, buttocks, and backs of the arms and this fat is very resistant to weight loss (Fig. 2). This deposition of fat is unique to human females and provides sufficient calories for gestation and the initial months of lactation (Frisch and McArthur 1974). It has been aptly termed “reproductive fat” for its functional value in maintaining a pregnancy and neonate (Lancaster 1986). Insufficient deposits of fat may both delay the onset of menstruation or result in its cessation if menarche has already occurred (Ellison 1990; Frisch and McArthur 1974). The accumulation of fat prior to puberty may contribute to the initiation of puberty, as leptin, a substance secreted by fat cells, appears to play a role in the activation of the HPG (Gueorguiev et al. 2001).

Girl's puberty further differs from that of boys as a result of the differential ordering of pubertal events. Although girls begin to go through puberty earlier than boys, they do not experience menarche and consistently ovulate until relatively late in the sequence of pubertal events. Girls must reach about 17–18 years of age before 80% of cycles are ovulatory, with maximal fertility not achieved until the mid-twenties (Apter and Vihko 1984; Bogin 2011). Boys, on the other hand, produce sperm relatively early (mean age = 13.3 years), even when they do not yet

Puberty in Girls,

Fig. 2 Fat distribution in a mature human female following the “fat spurt” at adolescence (Based on Lancaster 1986, and other sources)

possess the mature morphological features generally necessary to compete for mates and have been described as “fertile eunuchs” (Richardson and Short 1978). Therefore, girls possess the outward signs of reproductive maturity before they can conceive, but the opposite prevails for boys (Fig. 3). Different selective pressures have acted upon the timing of external morphological changes and gametogenesis (production of ova and sperm) in boys and girls. Late external development and small size in boys protects them from male competition and aggression by older males. But an undeveloped boy could fertilize a female should the opportunity arise, so the relatively early onset of spermatogenesis may have been favored by sexual selection. Girls’ adolescent subfertility has been attributed to an immature reproductive system, but subfertility does not occur to the same degree in all mammals or primates and may be a uniquely human adaptation. The development of breasts and acquirement of a distinct, relatively lower waist-to-hip (WHR) ratio as the pelvis widens at puberty, appear to signal fertility

to prospective mates and attract male attention (Singh 1993). Appearing outwardly mature before the consistent occurrence of ovulation may provide a period for assessment and choice of the best possible mate. Early external signals of maturity, coupled with relative infertility, may also increase a girl’s time for social development, formation of a social network, and the learning of childcare skills vital for offspring survival. Cognitive development, especially the acquirement of higher cognitive processes, and empathy are also heightened during adolescence. Based on the life histories of extant hunter-gatherer populations, such as the !Kung (see Howell 1979), it is likely that throughout much of human evolutionary history, most women had approximately two decades to acquire advanced cognitive, survival, parenting, and mate selection skills before becoming mothers.

Sequelae of Puberty in Girls and Variation in its Timing

The outward signs of girls’ physical maturity result in changes in family and social relationships. In many traditional societies, puberty is attended by ceremony and initiation rites to mark a girl’s impending fertility and passage into adulthood. Parents begin to treat daughters as more adult-like and restrict their activities more than those of their sons. Parents and offspring do not have completely overlapping genetic interests, referred to as *parent-offspring conflict*, and mothers may direct their daughter’s behavior to their own reproductive advantage (a form of *parental manipulation*, Alexander 1974). For example, adolescent girls may be given the responsibility of helping raise siblings at the expense of their own reproduction. To ensure the choice of an appropriate mate and increase the probability of surviving grandchildren, parents may heighten the supervision of their daughters, behavior referred to as *daughter-guarding* (Flinn 1988).

Changes in girl’s self-concept and sociosexual behavior also occur at puberty. Beginning in the 1960s, an extensive literature revealed consistent differences in relatively early versus later

Puberty in Girls, Fig. 3 Sequence and relative timing of pubertal events in modern girls and boys. “Adult Ovulation” refers to the occurrence of 80% ovulatory cycles.

“Spermarche” refers to the first appearance of spermatozoa in urine. “PHV” signifies peak height velocity (After Tanner 1962, and other sources)

maturing girls. Early puberty is associated with increased risk of depression and anxiety, poor body-image, eating disorders, early and risky sexual behavior, poor school performance, alcohol and drug abuse, early (teenage) pregnancy, early marriage, and divorce (Graber 2013; Negri and Susman 2011; Udry and Cliquet 1982). Pubertal timing also has significant medical and health consequences with earlier menarche related to an increased risk for mortality from all causes, especially breast cancer, obesity, insulin resistance, cardiovascular disease, and polycystic ovarian syndrome. Later age at menarche is associated with fractures and lower bone mineral density (Jacobsen et al. 2007). Such consistent differences in early and late maturing girls have spurred interest in the causes of variation in pubertal timing.

Genetic and Environmental Influences on the Timing of Puberty in Girls

The wide variation in girls’ pubertal timing is accounted for by both genetic and environmental

factors. Early studies of the concordance between female relatives in the age at menarche showed the closer the genetic relationship, the higher the concordance. Estimates of the heritability (proportion of phenotypic variation attributable to genetic variation) of menarche suggest that anywhere from 40% to 95% of the phenotypic variance in menarcheal age is due to genetic variance (Towne et al. 2005). Discrepancies in estimates occur because heritability is higher when environmental variance is reduced (e.g., in wealthy societies with equitable living conditions). As with most complex human traits, girls’ puberty is polygenic with over 40 different candidate genes or loci identified as contributing to menarche and its correlates, including height, obesity, and mineral bone density (Dvornyk and Waqar ul 2012). For example, genetic variation in and adjacent to the gene *LIN28* on chromosome 6, a gene conserved across species, is associated with pubertal timing (Ong et al. 2009). The major allele of the SNP rs314276 is associated with a faster growth spurt in height and shorter adult height in both sexes. In girls it is associated

with an earlier age at menarche and breast development and in boys, earlier appearance of pubic hair and voice breaking and more advanced pubic hair development. In addition to predisposing girls to earlier or later puberty, genes and their expressed neurobiological processes affecting pubertal onset may interact with environmental factors or affect sensitivity to them (Ellis et al. 2011; Schlomer and Cho 2017).

Aside from hereditary factors, a number of naturally occurring and human-introduced environmental factors appear to influence the timing of puberty and correlated life history characteristics in girls. These include access to good nutrition and health care, disease, exposure to estrogen-disrupting chemicals, and psychosocial factors. That well-nourished, healthy girls, with higher socioeconomic status, achieve menarche earlier than others has been well established (e.g., Eveleth and Tanner 1976). Improvements in sanitation, living conditions, and medical advances reducing the prevalence of diseases are believed to be involved in the earlier onset of puberty and increased height and weight observed from the mid-1800s to the last half of the twentieth century, referred to as the *secular trend*. Between 1830 and 1960 the average age at menarche dropped in Great Britain, Scandinavia, Germany, and the United States by approximately 3–4 months per decade (Eveleth and Tanner 1976). Similar declines were seen in other industrialized and some developing countries. Although the trend stabilized by the late 1900s, there is evidence of a more recent resurgence. On average puberty in modern girls occurs 3–4 years earlier than in their ancestral hunter-gathers and has become somewhat decoupled from psychosocial development. Reversals of the secular trend have been noted in countries experiencing famine and food shortages during the Second World War and more recently in Bosnia (Eveleth and Tanner 1976; Tahirovic 1998). Menarche is usually delayed in underfed children as well as in athletes and dancers with intentionally lean body mass, but advanced in obese girls (Ellison 1990; Frisch and McArthur 1974).

Synthetic chemicals employed in pharmaceutical products, manufacturing and industry, pest

control, and other environmental contaminants that disrupt, mimic, alter the rate of synthesis or block endocrine hormones, especially estrogen, alter the timing of puberty in girls and carry health risks (Lee and Styne 2013). Inadvertent exposure to chemical flame-retardants containing polybrominated biphenyls (PBS) through breastmilk and the use of estrogen cream by mothers, some hair tonics, and DDT are associated with early and precocious puberty. On the other hand, lead contamination is associated with later puberty. Public concern about the developmental and long-term health effects of these chemicals have led to increased regulation of their use in consumer products, farming, and industry.

Girls' pubertal development appears to be sensitive to the social, as well as the physical environment, with a number of psychosocial factors reliably correlated with the timing of girl's puberty. Girls experiencing stressful environments, family dysfunction, lack of parental support, absence of their biological father or low paternal investment, presence of a stepfather, and sexual abuse experience early menarche and its associated sequelae (e.g., Ellis et al. 1999; Ellis and Garber 2000; Moffitt et al. 1991; Noll et al. 2017; Surbey 1990; Webster et al. 2014). In addition absence of both biological parents, occurring in domestic and international adoption, is also related to early and precocious menarche (Parent et al. 2003; Surbey 1990). What accounts for these consistent relationships is not yet clear, but the supposition that natural selection equipped offspring with means to adjust development to best adapt to the environment in which they find themselves has inspired a number of hypotheses. A corollary that parents or other adults may alter an offspring's development in their own genetic interests has also been explored. One widely advanced hypothesis uniting a number of findings is that early childhood stress and reduced paternal investment result in children adopting a "fast" versus "slow" reproductive strategy of early sexual development and reproduction, with a focus on offspring quantity rather than quality, so as to offset the deleterious effects of a poor rearing environment (Belsky et al. 1991; Chisholm 1993; Ellis 2004; Surbey 1990). Another

hypothesis, based on the finding that the mothers of father-absent girls are also early maturers, is that a behavior-genetic effect underlies the relationship between father absence, early menarche, and their sequelae (Barbaro et al. 2017; Rowe 2002; Surbey 1990). An additional possibility is that, as observed in other mammals, inhibition of reproductive development in girls living with their biological fathers may serve as a mechanism of inbreeding avoidance, whereas exposure to unrelated adult males, such as stepfathers, may accelerate puberty, possibly via a pheromonal cue (Ellis and Garber 2000; Surbey 1990). That mothers may suppress the development of their daughters and recruit their aid in raising additional offspring, a form of parental manipulation, was previously discussed. Adaptations for coping with environmental stress may also play a role. Stress, depending on its timing, and whether it is physical, psychological, chronic, or acute, appears to have paradoxical results on puberty (Boyce and Ellis 2005; Boynton-Jarrett et al. 2013; Surbey 1990). For example, nutritional stress in childhood may initially delay growth as an adaptation to low energetic resources, but later result in advanced catch-up growth and early menarche once food supplies improve (Proos et al. 1991). Moreover, while stress usually inhibits the HPG, suppressing development and reproduction, glucorticoids released from the adrenal glands may counteract this inhibition (Matsuwaki et al. 2006) protecting and enhancing reproductive development in some stressful conditions. This may explain why chronic nutritional stress does not delay menarche indefinitely and why psychological stress and childhood sexual abuse is related to an earlier age at menarche, whereas physical abuse is related to both early and late age at menarche (Boynton-Jarrett et al. 2013).

Significance of Variation in the Timing of Puberty in Girls and Its Sequelae

Like many other human traits, such as height or intelligence, the timing of puberty in girls exhibits continuous phenotypic variation and plasticity. Evolutionary biologists generally attribute

phenotypic variation in life history traits to (a) *noise or random variance* due to environmental or genetic variance, (b) *adaptive plasticity* whereby a given genotype (genetic constitution) maintains fitness by producing the phenotype best suited for a given environment or condition (referred to as a conditional strategy), (c) *maladaptive plasticity* where a phenotype is pushed outside of the species-typical reaction norm with negative fitness consequences, or (d) *alternative life history strategies* whereby two or more distinct phenotypes or *morphs* are produced by different genotypes maintained by frequency dependent selection (Stearns 1992). A proportion of the variation in the timing of girls' puberty is certainly due to genetic or environmental variation that presently has no adaptive value or is vestigial. Maladaptive plasticity, such as that producing extremely precocious menarche from exposure to environmental contaminants, estrogen mimics, or growth-hormone additives in meat, accounts for another portion of variation. Alternative life history strategies usually refer to differences between species and are uncommon within species. Much of the remaining variation in girls' pubertal timing and correlated traits likely reflects the combined results of adaptive plasticity or the conditional strategies of offspring (or adults in their environment) serving to functionally match development with environmental conditions (Belsky 2000; Ellis 2004; Surbey 1998). Conditional strategies are triggered in response to environmental conditions with their phenotypic expression not directly associated with genotypic differences. The resulting developmental plasticity serving to adapt individuals to their current environments, without altering the underlying genetic infrastructure of life history traits, would tend to preserve the late Pleistocene species-specific life history of *H. sapiens* through historical changes in living conditions, such as those experienced by modern girls.

Conclusion

The life history of *H. sapiens* was constrained by the preadaptation of bipedalism and directional

selection for larger brain size during hominin evolution. The unique pattern of the human life history involves production of altricial young, a long period of dependency, late sexual maturity and first birth, wide birth spacing, low offspring number, and high levels of parental and post-reproductive investment. The characteristics, timing, and sequelae of puberty in girls are one component of the human life history and exhibit similar, but also unique features compared to that of other female primates. Girls' puberty differs significantly in tempo, sequence, and expressed phenotypic characteristics to that of boys. The timing of puberty in girls shows considerable genetic and environmental variation and is related to girls' psychological, social, and reproductive development, and health. Application of a number of evolutionary theoretical concepts and models enhances our understanding of the significance of the unique characteristics and observed variation of pubertal timing in girls.

Definition

A public record is a document that has few restrictions on access. Public records are required by law to be created, stored, and available. Public records are created in the performance of duty from government officials.

Introduction

Public records such as census data and business records are available for access by the public. Online resources such as [Archives.gov](https://www.archives.gov) and [PACER.gov](https://www.pacer.gov) increase availability of access to the majority of people (for more, see section on Online Resources for Public Records). Not all public records are available online; however, there has been a recent increase in use of online records due to their accessibility. Social scientists are among the most frequent users of these public records databases. This entry details types of public data and availability in the United States, issues with public records, use of public records, and recommendations for future uses of public records in evolutionary psychology.

Availability and Use of Public Records

Some public records are available to only a small subset of individuals who spend hours searching physical archives for the information they are seeking. However, other public records are available online and are relatively easy to find with an online search.

Types of Public Records

Though state guidelines differ (Winkler and Byers 2010), under the federal Freedom of Information Act (FOIA, see section on FOIA below), the following types of information are considered public record:

- Birth Records
- Census Data
- Consumer Protection Information
- Copyrights and Patents
- Court Dockets
- Criminal Records
- Death Records
- Federal Legal Cases
- Government Publications
- Government Spending Reports
- National Health Statistics
- Professional and Business Licenses
- Real Estate Records

- Sex Offender Registry
- Voter Registration

Additionally, certain federally funded scientific research is also mandated to be publicly available (U.S. Department of Health and Human Services 2016; U. S. Government Publishing Office 2009). These publications are available through PubMed.

Online Resources for Public Records

There are an abundance of online resources of public record information. The National Archives and Records Administration (NARA; <https://www.archives.gov>) maintains the most comprehensive collection of public record data in the United States. NARA's website includes a searchable database of public record information. Some information is available online, and requests can be made for information that is not available online. Other national resources of public record data are listed below with the types of information you can find on those databases. Some of these databases have raw data, while other resources provide aggregated data and infographics.

- Environmental Protection Agency (<https://www.epa.gov>)
 - Toxic release inventory, hazardous waste sites
- Federal Bureau of Investigation (<https://www.fbi.gov>)
 - Crime statistics, sexual offender registry
- Federal Bureau of Prisons (<https://www.bop.gov>)
 - Inmate locator
- Federal Election Commission (<http://www.fec.gov>)
 - Campaign finance reports
- Government Publishing Office (<https://www.gpo.gov>)
 - Official information products of the US government such as official publications of Congress, the White House, and other federal agencies
- Internal Revenue Service (<https://www.irs.gov>)
 - Tax exempt organizations
- National Center for Health Statistics (<https://www.cdc.gov/nchs>)

- Data from national health surveys such as statistics on the prevalence and incidence of diseases, conditions, and health care
- Public Access to Court Electronic Records (<https://www.pacer.gov>)
 - A national index for the US district, bankruptcy, and appellate courts
- PubMed (<https://www.ncbi.nlm.nih.gov/pubmed>)
 - More than 26 million citations from MEDLINE and other science resources
- Securities and Exchange Commission (<http://www.sec.gov>)
 - Corporate filings
- Statue of Liberty – Ellis Island Foundation, Inc. (<http://www.libertyellisfoundation.org>)
 - Immigration records from Ellis Island
- United States Census Bureau (<https://www.census.gov>)
 - Index of data collected through the United States Census every 10 years
- United States Copyright Office (<http://www.copyright.gov>)
 - Records of copyrighted books, music, art, and periodicals
- United States Patent and Trademark Office (<https://www.uspto.gov>)
 - Index of existing and published patents

The Evolution of Societies and the Need for Public Records

During the majority of human evolution, we lived in small-scale societies where it was relatively easy to remember past interactions with your community. However, after the advent of agriculture some 10,000 years ago, humans were able to live in larger and larger settlements, including the megacities of today. During this transformation, it also became possible for people to specialize in a particular trade and have a division of labor. Once our communities became too large for us to remember all interactions with all people, particularly in the domain of resource exchanges, it became necessary to have some way of accounting for economic interactions with strangers (Basu and Waymire 2006). The earliest record keeping dates back to 8000 BC, when ancient Sumerians used tokens as an accounting tool. Since that time, all large-scale

human societies have kept records in some form or another.

In addition to keeping records for accounting purposes, we started keeping written records to keep track of other facets of large-scale society life including population growth and change, ownership of land, laws, marriages, and more. Some of these written records were kept for historical significance; other records were for book-keeping purposes. As we began recording more and more information, a significant challenge emerged in terms of organizing and archiving these records.

In the modern era, developing a central location for public records with a systematic method for maintaining documentation is still a concern. In the early 1900s, physical public records were often scattered in government buildings, making it difficult to access and secure them (Atherton 1979). Due to these challenges, a system of organizing and maintaining records was developed. The National Archives and Records Administration in the United States is responsible for maintaining public records.

Freedom of Information Act

In the United States, The Freedom of information Act was enacted on July 4, 1966, and was effective one year after the enactment ([FOIA.gov](https://www.foia.gov)):

Since 1967, the Freedom of Information Act (FOIA) has provided the public the right to request access to records from any federal agency. It is often described as the law that keeps citizens “in the know” about their government. Federal agencies are required to disclose any information requested under the FOIA unless it falls under one of nine exemptions which protect interests such as personal privacy, national security, and law enforcement ([FOIA.gov](https://www.foia.gov)).

Issues with Availability of Public Information

There are some concerns about the availability of public information. On one hand, transparency of information is important for public safety, law enforcement, and problem solving on a national level. On the other hand, privacy and restriction of access to individual data seem to be of most concern to the public (Munson et al. 2012). These concerns have been exacerbated by the

availability of public records online (Blankley 2004). Additionally, people seem to be divided on the issue of access: the slim majority believes availability should stay as is, with others believing in some form of reform. Availability of sensitive personal information increases risk of identity theft. For example, in 2015, a former Florida Governor released hundreds of thousands of emails that were considered public record; however, some documents contained sensitive data such as social security numbers, addresses, emails, and protected health information (Sottek 2015). According to Florida law, the social security numbers should have been redacted but were included due to human oversight. If criminals access sensitive information gathered from public records, they can steal and sell individual identities. However, those supporting the Freedom of Information Act, such as employers and lawyers, feel that transparency is needed for accountability in government (Munson et al. 2012).

Use of Public Records

Users of public records fall into a few distinct categories: individual information seekers and aggregate data for the purpose of diagnosing trends (Adams 2007). However, metadata or aggregated data is not considered public record in some states (Cockerham 2009). Individual use of NARA has resulted in an increase of requests for reproductions of archival records (Adams 2007). Other than personal inquiries, academics and researchers from public and private venues are among the most frequent users of public records for research with less use by historians than might be predicted. From 2001 to 2004, researchers accounted for nearly 90 % of fulfilled requests for reproduction of electronic records.

Since researchers are the most frequent users of archival data and public records, it has been suggested that collaboration between NARA and social science data archives would be valuable for productive research programs that could employ the use of both of these sources (Adams 2007). One archive of social science data is the International Association for Social Science Information Service and Technology (IASSIST). This professional organization aids in maintaining social science data records for uses in research and

education. Currently, the Library of Congress sponsors the Digital Preservation Program of the National Digital Information Infrastructure and Preservation Program that maintains several major social science data archives in the United States.

Evolutionary psychologists often turn to public records to test evolutionary hypotheses about human behavior that would be nearly impossible to explore without archival data. For example, Daly and Wilson (1988) used public records from thirteenth-century England and from modern Detroit to demonstrate that kinship plays a suppressive role in homicides. That is, people are far more likely to kill non-kin than kin. This suggests that even in the realm of criminal activity, the evolutionary pressure to support kin plays a role in shaping human behavior. Similarly, marriage records from nineteenth-century Sweden have been used to test predictions from behavioral ecology regarding resources and reproductive potential (Low 1991).

In another example, researchers used census and CDC data to calculate personalized estimates of risk. By dividing the number of people living with HIV by the population, the researchers calculated the base rate of HIV in the United States (Ellis and Brase 2015; Ellis et al. 2014). People largely ignore base rate information, and this can lead to errors in judgment and resulting decision-making (Kahneman et al. 1982). However, by tailoring base rate information to individuals, it is argued that individual models of risk will lead to more optimal outcomes (Gail et al. 1989).

Thus, public records can be a valuable resource for creating models of existing behaviors, testing evolutionary hypotheses, predicting behavior across contexts, and providing solutions for change toward optimizing behavior. Furthermore, using public records gives evolutionary psychologists the ability to study these patterns cross-culturally.

Future Research in Evolutionary Psychology Using Public Records

Regardless of the issues of privacy, researchers can benefit from the use of public records to answer research questions in evolutionary psychology. Evolutionary psychologists should

continue to use public records in the context of testing hypotheses from behavioral ecology and other evolutionary theories. Aside from the examples mentioned above, there are new uses and types of public records emerging with the aid of technology. For example, the CDC publishes the data from the annual Behavioral Risk Factor Surveillance System (BRFSS) that has been conducted since 1984 and is the largest continually collected health survey in the world (<http://www.cdc.gov/brfss/>). This will be a rich source for testing evolutionary hypotheses related to health. We expect that similar databases will become available in the coming years. Thus, evolutionary psychologists should stay abreast of the available resources for accessing public records.

Conclusion

Public records are available in digital and physical formats. The availability of public records varies by type and location. Multiple organizations and institutions were created to manage and maintain public records for use. Social scientists and other researchers comprise the majority of seekers of public records. There has been some use of public records in evolutionary psychology (e.g., census data, business archives). However, future research should focus on expanding its use and capitalizing on the wealth of information available through public records.
